The production of residual topography, as it involves the entire crust, resembles a buckled elastic plate. Even though such topography will necessarily be associated with large free-air gravity anomalies, the forces responsible for the deformation remain in mechanical and isostatic equilibrium at all times as evidenced by the equal positive and negative components of both the topography and free-air gravity anomaly. Formation of residual topography by the flexural interference of thermally modified lithosphere is here termed 'thermo-mechanical hysteresis' (TMH). It is suggested that TMH may be responsible for the characteristic free-air gravity anomalies observed over extinct spreading centres, for example, within the South China Sea and the Coral Sea basins, the isostatic gravity anomaly observed across the ocean/continent boundary of many passive margins, for example Argentina and the northeastern US margins, and anomalous bathymetric trends within the major

oceanic plates, for example, the linear bathymetric trend associated with the Cocos-Keeling Islands in the Indian Ocean.

Structure of the lithosphere

The interdependence of the thermal structure of the lithosphere and its mechanical properties has been convincingly demonstrated by recent studies of loading within the oceans and continents¹⁻⁵. Furthermore, these studies have established that flexure is the predominant mechanism by which emplaced loads are supported by the lithosphere. The form of the support is dependent on the lithospheric rigidity, which itself increases with lithospheric age. Generally, in the oceans, the plate age defines the thermal structure of the lithosphere through the cooling plate model⁶, while in the continents, rather than absolute plate age being important, it is the time since the last major thermal event as defined by either reset radiometric base-metal ages¹ or episodes of extensive alkalic or basic volcanism⁷.

Observations of the subsidence of seamounts associated with intraplate swells suggest that the swells behave like oceanic crust reset to a younger thermal age^{2,8-11}. The swells, in turn, are related to the broad-scale heating and hence thermal expansion of the lithosphere above hotspots (for example, Hawaii, Snake River province) or hot-lines (for example, Easter Island chain¹², eastern Australia^{13,14}). Thermal rejuvenation results in a lithosphere with properties identical to that of normal lithosphere but with an apparent younger thermal age and correspondingly lower lithospheric rigidity².

Thermal modification of the lithosphere by a general heating event causes an immediate isostatic uplift in an attempt to compensate the thermally expanded lower lithosphere^{14,16}. Isostatic compensation is essentially supplied by a Pratt-type pro-

Fig. 1 Schematic representation of the initial rigidity structure of the lithosphere, the distribution of the heating function (parametrized by ΔH_{\max} and σ), the initial thermal structure over the zone of maximum heating and in the distant regions of the plate, and the mechanical recovery of the lithosphere (that is, the variation of T_e , the effective elastic thickness of the lithosphere) with time.

cess in which the uplifted topography compensates the lower densities associated with the thermally modified lithosphere. Even though Pratt isostasy is a local compensation scheme, the form and maximum amplitude of the surface deformation will be determined by the minimum lithospheric rigidity obtained during the thermal resetting process (in both space and time). Because plate rigidity is defined by the depth to a particular isotherm (in this case, the 450 °C isotherm⁵), minimum rigidity resetting occurs some time after the initiation of cooling as heat is removed vertically from the lower lithosphere to the upper lithosphere (Fig. 1). Second, minor heating associated with lateral heat flow eventually modifies rigidities in the distant regions of the plate. Following the maximum deformation stage, cooling of the lithosphere by vertical and lateral heat flow will result in a spatially and temporally varying flexural rigidity. In particular, the temporally increasing flexural rigidity will produce a progressively broader subsidence with time relative to the initial uplift. Flexural interference between this initial uplift and subsequent broader subsidence results in a residual topography. The purpose of this article therefore, is to model quantitatively the thermo-mechanical response of the lithosphere due to thermal loading and to define the production and form of residual topography.

Thermal loading

Several studies have suggested that mid-plate swells are adequately approximated by a gaussian-type heating function¹⁰. For convenience, the same functional form will be assumed for the distribution of the thermal load in this study. Heat input into the lithosphere can be characterized by the dimensionless quantity¹⁶ ΔH , where $\Delta H = 1$ represents complete melting of the lithosphere while $\Delta H = 0$ represents stable thermal equilibrium within the lithosphere. The degree of lithospheric heating can also be expressed in terms of the lithospheric stretching function of McKenzie¹⁵, and, in particular, the two-layer stretching model of Royden and Keen¹⁶, even though no literal stretching is implied. In particular,

$$\Delta H = (1 - 1/\beta) \left(\frac{a - t_c}{a} \right)^2 \exp[-x^2/\sigma^2]$$

$$\Delta H_{\max} = 0.5, \quad \beta_{\max} = 2.5$$

where ΔH_{\max} is the maximal thermal heating, β is typically the stretching of the sub-crustal lithosphere, σ is the half-width of the heating function (with modelling constants defined in Table 1), a is the lithospheric thickness, t_c the oceanic crustal thickness and x is the horizontal coordinate. As the lithosphere/asthenosphere boundary represents an isotherm (T_m), β can define not only the degree of sub-crustal stretching, but also the maximum

vertical migration of this temperature boundary and therefore the degree of subcrustal heating. The use of β does not necessarily imply a tectonic process or setting. However, the actual details of the heating process or the distribution of the thermal anomaly itself are not critical to this argument. Whenever a load, thermal or otherwise, is removed incrementally from the lithosphere while the flexural rigidity is varied, a permanent lithospheric deformation results. This article links the thermal loading (and subsequent unloading as the load is conductively dissipated) of the lithosphere with its thermal and hence mechanical modification (and subsequent recovery). By calculating $\beta(x)$ from ΔH , the initial (or instantaneous) surface uplift is¹⁷,

$$S_i = \frac{\alpha \rho_m T_m}{2(\rho'_m - \rho_w)} \Delta H(x)$$

where α is the thermal expansion coefficient, and ρ_m , ρ'_m and ρ_w are the mantle density at 0 °C, the asthenosphere density and the water density, respectively.

The initial surface uplift S_i , assumes that the lithosphere has zero flexural strength (Pratt or local isostasy) and is termed the

Table 1 Modelling parameters used

Parameter value	Definition
$a = 125$ km	Lithospheric thickness
$t_c = 6$ km	Oceanic crustal thickness
$\kappa = 0.008$ cm ² s ⁻²	Thermal diffusivity
$\alpha = 3.4 \times 10^{-5}$ °C ⁻¹	Thermal expansion coefficient
$T_m = 1,333$ °C	Temperature defining lithosphere
$\tau = 62.8$ Myr	Thermal relaxation coefficient
$Z_e = 450$ °C	Controlling elastic isotherm
$\rho_w = 1.03$ g cm ⁻³	Water density
$\rho_s = 2.5$	Sediment density } ρ_i
$\rho_m = 3.33$	Mantle density at 0 °C
$\rho'_m = \rho_m(1 - \alpha T_m)$	Asthenosphere density
$= 3.179$	
$g = 982$ cm s ⁻²	Acceleration due to gravity
$\gamma = 6.673 \times 10^{-8}$ cm ³ g ⁻² s ⁻²	Gravitational constant
$\Delta H_{\max} = 0.5$	Maximum thermal heating
$\beta_{\max} = 2.5$	Equivalent sub-crustal stretching value
$\sigma = 50$ km	Standard deviation of heating function
$D = ET_c^3/12(1 - \nu^2)$	Lithospheric rigidity
T_e	Effective elastic thickness
$E = 6.5 \times 10^{11}$ dyn cm ⁻²	Relaxed Young's modulus
$\nu = 0.25$	Poisson's ratio

Fig. 2 Following a thermal event, the driving subsidence associated with the cooling and contraction of the lithosphere opposes the initial uplift, itself associated with a thermal buoyancy force. The resulting time-dependent force balance is subsequently modified by the mechanical properties of the lithosphere, producing a time-varying surface topography. The surface topography is illustrated for various assumptions of the mechanical response of the lithosphere at 0, 4, 9, 16, 25, 49, 64, 81 and 100 Myr since the initiation of cooling. Modelling parameters are defined in Table 1. *a*, Surface response of the lithosphere assuming a local isostatic response to loading. As local compensation refers to a zero-rigidity lithosphere, the form of the surface response is equivalent to the resultant force acting on the lithosphere. As lithospheric cooling has been modelled using both vertical and lateral heat flow, the force spreads laterally with time. *b*, Surface response of the lithosphere assuming a constant rigidity. If the thermal event fails to reset the lithospheric rigidity, the uplift and subsidence histories are identical and therefore no residual topography is produced. *c*, Surface response of the lithosphere assuming that its rigidity is reset and subsequently increases with time following the thermal event. The differing uplift and subsidence histories of the lithosphere result in a residual topography, the amplitude and wavelength of which relates to the pre-event rigidity and the degree of resetting. *d*, Surface response of the lithosphere assuming both a spatial and temporal variation in rigidity. The spatial rigidity variations relate to the distribution of the thermal event whereas the temporal variations relate to the thermal properties of the lithosphere. Note that in both *c* and *d* the topographic wavelength decreases with time, implying a progressive decrease in flexural rigidity. Such behaviour is usually interpreted in terms of the flexural response of a (Maxwell) visco-elastic plate to loading. However, in this case, the changing topographic wavelength is simply reflecting the sensitive interrelationship between the mechanical properties of the lithosphere and its temperature structure.

'local uplift'. Although Pratt isostasy (or any local isostatic scheme) generally represents an unrealistic response of the lithosphere to loading, it is very useful in describing the potential uplift of the lithosphere. Convolution of this local uplift with a flexural filter redistributes the surface uplift according to the mechanical properties of the lithosphere. For example, if the lithosphere has constant elastic rigidity D , then the surface uplift is given by (in the frequency domain)¹⁸,

$$S_i^* = \frac{\alpha \rho_m T_m}{2(\rho'_m - \rho_w)} \Delta H(k) \left[1 + \frac{Dk^4}{(\rho_m - \rho_i)g} \right]^{-1}$$

where ρ_i is the density of material infilling the deformation, k is the wavenumber, and g is the acceleration due to gravity. As a consequence of thermally modifying the temperature structure of the lithosphere, D is not constant but varies both spatially and temporally in the plate such that $D = D(x, t)$, t being the time since the initiation of lithospheric cooling.

Cooling of the lithosphere by the vertical and lateral flow of heat away from the thermally perturbed zone results in the creation of an opposing subsidence which progressively negates the initial surface uplift. The local subsidence counteracting S_i is given by¹⁹,

$$S_t(x, t) = \frac{2\rho_m \alpha T_m a}{(\rho'_m - \rho_m)} \sum_{n=1}^{\infty} \frac{2}{n^2 \pi^2} A_n^* (1 - e^{-n^2 t / \tau})$$

where

$$A_n = \frac{1}{n\pi} \{ (1 - \beta) \sin(n\pi z_1) + \beta \sin(n\pi z_2) \}$$

$$z_1 = t_c / a, \quad z_2 = z_1 + (1 - z_1) / \beta$$

$$A_n^* = A_n * X(x, t)$$

$$X(x, t) = \frac{1}{2(\pi \kappa t)^{1/2}} \exp[-x^2 / 4\kappa t]$$

where $X(x, t)$ represents the lateral conduction of heat, A_n the Fourier series of the initial vertical lithospheric temperature

distribution, $*$ the convolution operation, and τ is the thermal relaxation coefficient. As before, the actual subsidence is calculated by convolving $S_t(x, t)$, the local subsidence, with the lateral variations of lithospheric rigidity to give S_t^* . Figure 2a summarizes the spatial and temporal behaviour of the local thermal uplift (maximum value of 2,380 m) within the lithosphere for $\Delta H = 0.5$ ($\beta_{\max} = 2.5$) and $\sigma = 50$ km (and for times n^2 Myr since initiation of cooling, $1 < n < 10$) and clearly shows the effects of both vertical and lateral heat flow. Because the isostatic compensation in this example is assumed to be local, the uplift is proportional to the thermally generated buoyancy force acting on the lithosphere. With infinite time, the residual local uplift ($S_i - S_t(x, t)$), and therefore the buoyancy force, are identically zero everywhere.

Lithospheric subsidence

Referring to Fig. 2, we can monitor the subsidence of the lithosphere following a thermal event for a variety of mechanical conditions. If we insist on the mechanical homogeneity of the lithosphere both laterally and with time, the residual subsidence ($S_i^* - S_t^*(x, t)$) will again be reduced to zero given sufficient time even with flexural redistribution of the surface uplift (Fig. 2b). With $T_e = 20$ km and after 100 Myr, a topographic surface with amplitude 254 m is all that remains from an initial uplift of 1,824 m. If, however, we relax the requirement for temporal homogeneity of the lithospheric rigidity, then the flexural modification of the local subsidence changes continually with time. In this example, the pre-event effective elastic thickness of T_e (42.2 km) is thermally reset to 20 km. Mechanical recovery of the lithosphere over a 100-Myr period increases T_e from 20 to 36.9 km (Fig. 1), producing significant residual topography (431 m, Fig. 2c) relative to Fig. 2b.

Thermal modification of the lithospheric temperature structure will obviously be greatest nearest the thermal perturbation. Necessarily, therefore, the mechanical properties of the lithosphere must be a function not only of time since the initiation of cooling, but also of the distance from the perturbation. The

redistribution of the local subsidence, $S_i(x, t)$, by a heterogeneous elastic plate to give the flexural subsidence, $S_i^*(x, t)$ is given by,

$$\frac{\partial^2}{\partial x^2} \left[\frac{D(x, t)}{(\rho_m - \rho_l)g} \frac{\partial^2}{\partial x^2} S_i^*(x, t) \right] + S_i^*(x, t) = S_i(x, t)$$

The lateral and temporal variations of plate rigidity, $D(x, t)$, are calculated by monitoring the depth to the 450 °C lithospheric isotherm⁵. The above differential equation is most conveniently solved using a finite-difference algorithm²⁰. The resulting topography ($S_i^* - S_i^*(x, t)$) is now the result of a complex interaction between vertical and lateral heat flow and the spatial variations of plate rigidity about the thermal anomaly. Figure 2d represents the full model prediction for thermally reset oceanic lithosphere, producing in this example residual topography of 335 m. While the residual topography is only relatively small (100–200 m), note that this deformation was produced with only a modest degree of sub-crustal heating. Areas associated with high-temperature contrasts, such as during the creation of a passive continental margin or during the death of a mid-oceanic spreading centre, will enhance this hysteresis effect and, while probably never dominating, will always be a complicating factor in loading situations when heat is involved.

Apparent visco-elastic behaviour

A curious feature of the residual topography in Fig. 2c, d is that the wavelength appears to decrease progressively with time implying, therefore, an apparent decrease in flexural rigidity with time even though we are able to monitor its actual increase. That is, the surface deflection is mimicking the temporal response of a visco-elastic (Maxwell) plate. This observation simply underlines the sensitive interrelationship between lithospheric temperature structure and its flexural response and may prove to be useful in rationalizing the apparent contradiction posed by those flexural studies which vehemently refute the elastic model in favour of a visco-elastic (Maxwell) model^{21–26}.

Apparent visco-elastic behaviour of the lithosphere is not limited to TMH. McNutt²⁷, in her analysis of seamount flexure, noted that load rejuvenation occurs as the heat introduced into the lithosphere during seamount emplacement is vertically redistributed. The degree of load rejuvenation is therefore sensitive to the level at which the temperature anomaly is introduced. Similarly, foreland basins, produced as an isostatic response to thrust sheet/nappe emplacement²³, modify the temperature structure of the foreland lithosphere (at a rate determined by the thermal diffusivity of the lithosphere) as the overlying sediment infill and thrust sheets thermally re-equilibrate²⁸. In both cases, lithospheric heating induces a decrease in rigidity with time which mimics the behaviour of a Maxwell visco-elastic plate.

While thermo-mechanical hysteresis is concerned with load removal during cooling of the lithosphere, a similar flexural interference is obtained during (non-thermal) load emplacement. For example, Liu *et al.*²⁹ successfully modelled the negative gravity anomaly over the 85° E ridge by investigating the flexural interference between the basement deformation produced by the formation of the ridge and the regional deformation associated with its subsequent burial by sediments. Thermo-mechanical hysteresis, therefore, is only a special case of the flexural interference of lithospheric deformations associated with temporally and/or laterally varying loads and a temporally varying lithospheric rigidity.

Isostatic equilibrium

The isostatic state of the heated lithosphere will be a complicated interaction between the Pratt effect of the thermally modified subcrustal lithosphere and the regional isostatic effect of the evolving crustal deformation. In the limit, however, only the crustal deformation remains. Figure 3 illustrates the residual topography and associated free-air gravity effect produced by thermal re-equilibration of oceanic lithosphere over a 400-Myr period since cooling and for all practical purposes, represents

Fig. 3 The resultant free-air gravity effect and residual surface topography following thermal re-equilibration of the lithosphere ($t = 400$ Myr) in which the original thermal perturbation modified both the spatial and temporal flexural properties of the lithosphere. The residual topography and its free-air effect remain an isostatic process in the sense that the topography and free-air gravity laterally integrate to zero (remembering that the Moho parallels the surface).

complete thermal re-equilibrium of the lithosphere. If, during the thermal event, the lithospheric rigidity failed to be reset (that is, remains constant), no residual topography (and hence gravity effect) would be produced. In contrast, any rigidity variation (in space or time) results in a residual topography, in this example being 162 m with a corresponding free-air gravity effect of 20 mGal. Compensation is maintained by the strength of the lithosphere, not in the usual way, but by the production of a surface deformation which laterally integrates to zero (here termed mechanical equilibrium).

Applications

Thermo-mechanical hysteresis results from the thermal re-equilibration of the lithosphere following a heating event. This concept, when applied to the oceanic lithosphere in particular, may help to explain several anomalous bathymetric and gravimetric trends within the Indian Ocean (for example, Cocos-Keeling Islands and associated bathymetric trends), extinct spreading centres (for example, Coral Sea Basin) and ocean/continent boundaries of passive margins (for example, Argentinian margin). No attempt has been made to model the bathymetry or gravity anomalies in detail, but the similarity in characteristics predicted by thermo-mechanical hysteresis, namely, low-amplitude but long-wavelength topography, relatively large-amplitude free-air gravity anomalies relative to the topography (or equivalently, an anomalously high gravitational admittance) and an isostatic compensation reminiscent of mechanical isostasy (a balanced deformation of the entire crust generally reported as uncompensated topography), and the above geological features, strongly suggests that the same process, TMH, may be operative.

Cocos-Keeling hotspot trend

Anomalous north-east-south-west trending bathymetry (1–2 km) within the northern Indian Ocean and generally paralleling the absolute motion of the Indo-Australian plate (Fig. 4a) is associated with the Cocos-Keeling Islands, the trend and islands being produced by a presumed hotspot of Lower Tertiary age. Although the bathymetry of the trend is minor relative to the Ninety-East Ridge, the associated free-air gravity anomaly is excessively large (Fig. 4a). To remove the effect of the Cocos-

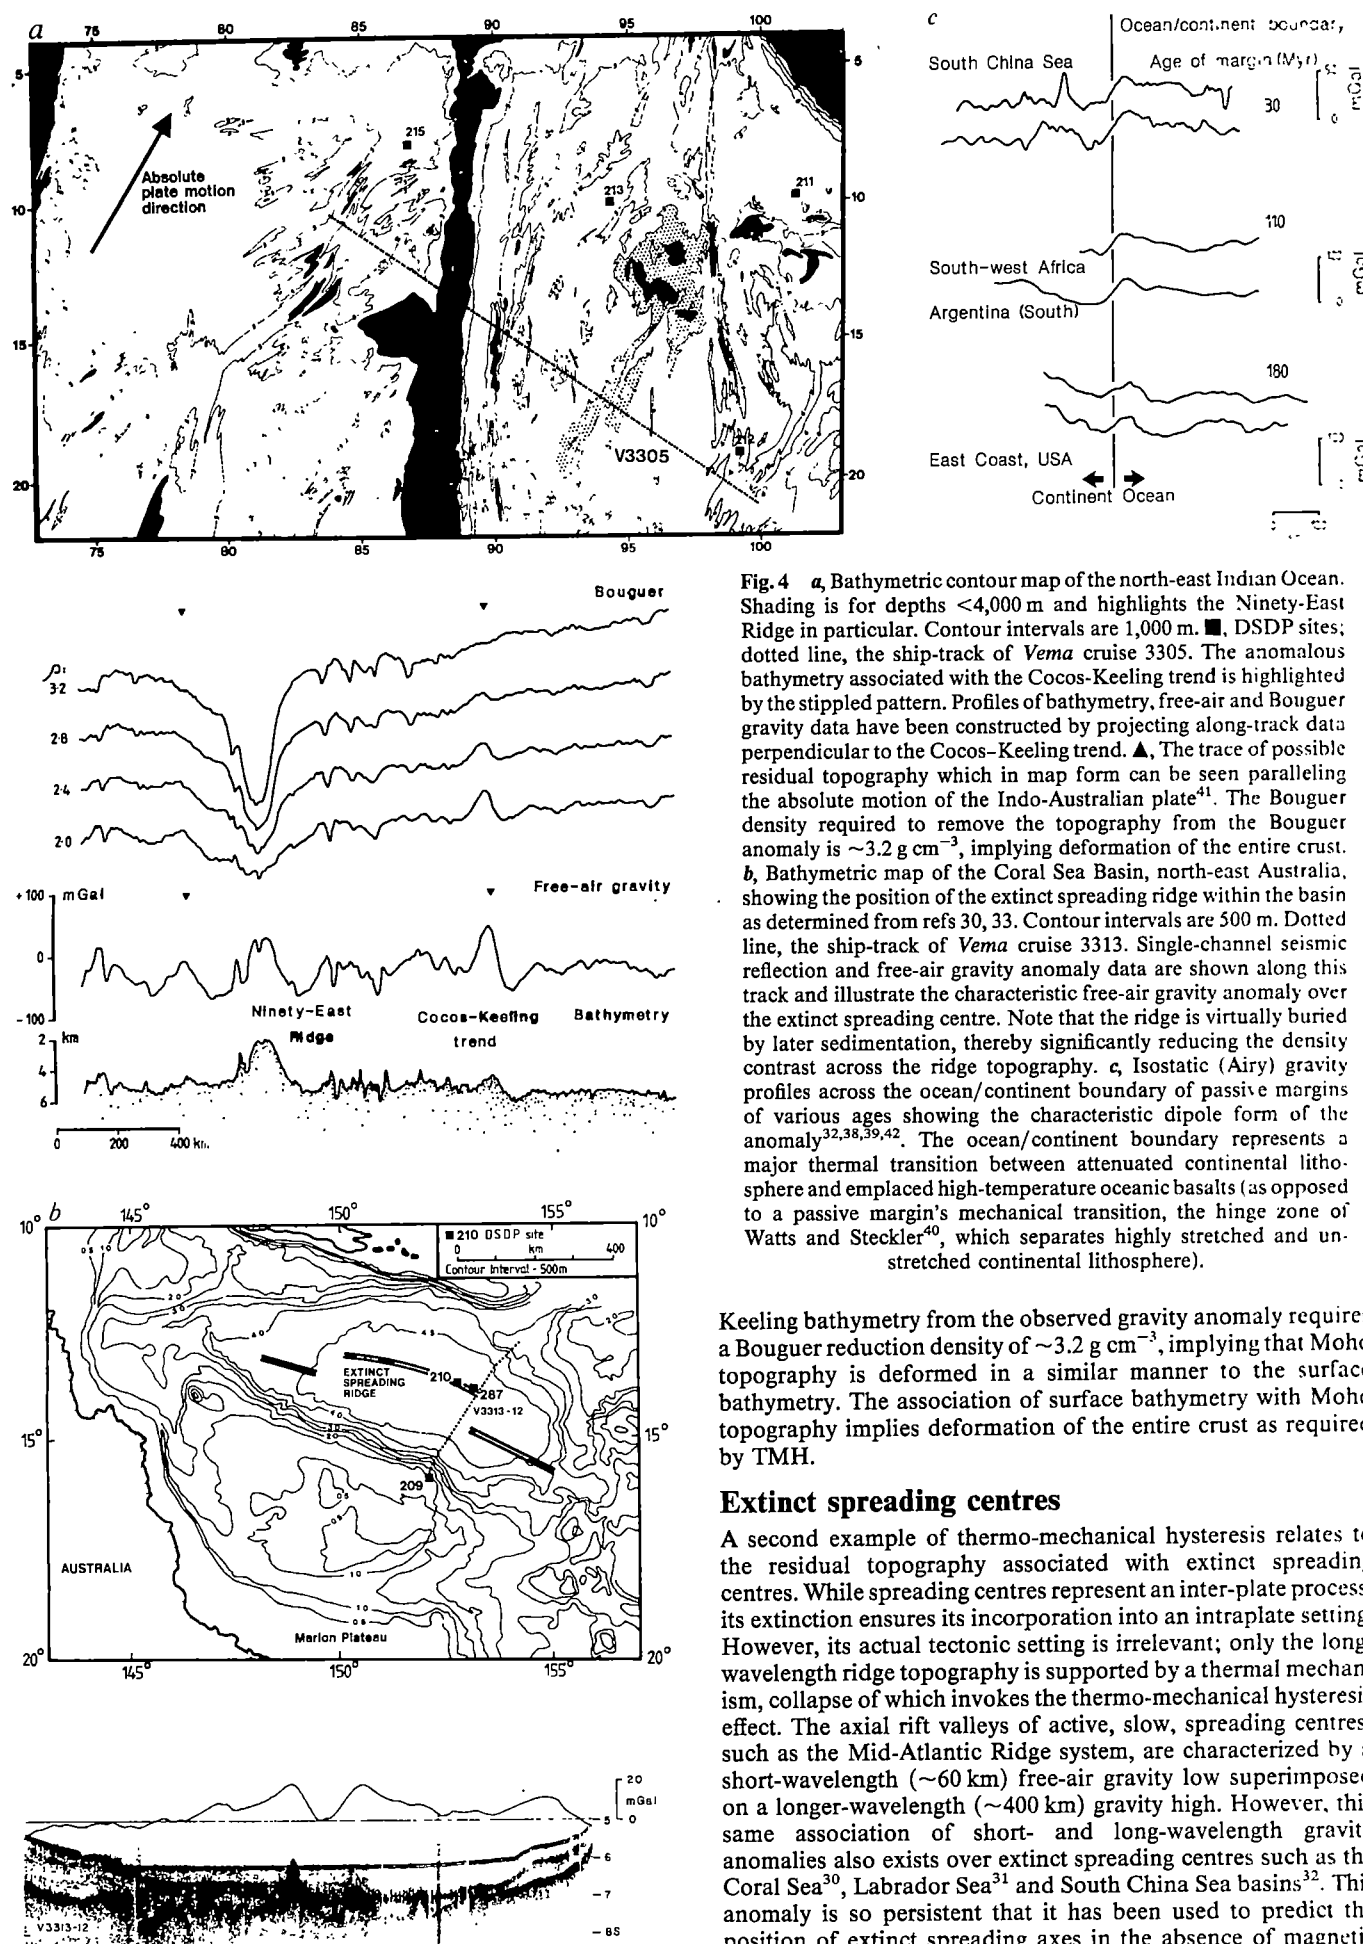

Fig. 4 *a*, Bathymetric contour map of the north-east Indian Ocean. Shading is for depths <4,000 m and highlights the Ninety-East Ridge in particular. Contour intervals are 1,000 m. ■, DSDP sites; dotted line, the ship-track of *Vema* cruise 3305. The anomalous bathymetry associated with the Cocos-Keeling trend is highlighted by the stippled pattern. Profiles of bathymetry, free-air and Bouguer gravity data have been constructed by projecting along-track data perpendicular to the Cocos-Keeling trend. ▲, The trace of possible residual topography which in map form can be seen paralleling the absolute motion of the Indo-Australian plate⁴¹. The Bouguer density required to remove the topography from the Bouguer anomaly is $\sim 3.2 \text{ g cm}^{-3}$, implying deformation of the entire crust. *b*, Bathymetric map of the Coral Sea Basin, north-east Australia, showing the position of the extinct spreading ridge within the basin as determined from refs 30, 33. Contour intervals are 500 m. Dotted line, the ship-track of *Vema* cruise 3313. Single-channel seismic reflection and free-air gravity anomaly data are shown along this track and illustrate the characteristic free-air gravity anomaly over the extinct spreading centre. Note that the ridge is virtually buried by later sedimentation, thereby significantly reducing the density contrast across the ridge topography. *c*, Isostatic (Airy) gravity profiles across the ocean/continent boundary of passive margins of various ages showing the characteristic dipole form of the anomaly^{32,38,39,42}. The ocean/continent boundary represents a major thermal transition between attenuated continental lithosphere and emplaced high-temperature oceanic basalts (as opposed to a passive margin's mechanical transition, the hinge zone of Watts and Steckler⁴⁰, which separates highly stretched and unstretched continental lithosphere).

Keeling bathymetry from the observed gravity anomaly requires a Bouguer reduction density of $\sim 3.2 \text{ g cm}^{-3}$, implying that Moho topography is deformed in a similar manner to the surface bathymetry. The association of surface bathymetry with Moho topography implies deformation of the entire crust as required by TMH.

Extinct spreading centres

A second example of thermo-mechanical hysteresis relates to the residual topography associated with extinct spreading centres. While spreading centres represent an inter-plate process, its extinction ensures its incorporation into an intraplate setting. However, its actual tectonic setting is irrelevant; only the long-wavelength ridge topography is supported by a thermal mechanism, collapse of which invokes the thermo-mechanical hysteresis effect. The axial rift valleys of active, slow, spreading centres, such as the Mid-Atlantic Ridge system, are characterized by a short-wavelength ($\sim 60 \text{ km}$) free-air gravity low superimposed on a longer-wavelength ($\sim 400 \text{ km}$) gravity high. However, this same association of short- and long-wavelength gravity anomalies also exists over extinct spreading centres such as the Coral Sea³⁰, Labrador Sea³¹ and South China Sea basins³². This anomaly is so persistent that it has been used to predict the position of extinct spreading axes in the absence of magnetic

anomalies^{32,33}. Once spreading has ceased within a rift axis, heat is rapidly dissipated, allowing the ridge topography to subside and thereby destroying its characteristic waveform. In general, the isostatic compensation of spreading ridge topography is poorly understood. Interpretation of admittance functions obtained across active spreading systems^{34,35} suggests low lithospheric strengths ($T_e < 10$ km). Seismic studies have shown, however, that oceanic crust is of normal thickness at least to within ~ 10 m of the ridge axis³⁶. As the crustal thickening predicted by isostatic models (in which ridge topography is represented as a surface load) is not observed, such models fail to describe adequately the isostatic state of the ridge. The most promising approach has been to model the ridge topography as the response of a broken elastic plate to a sublithospheric buoyancy force³⁷, analogous to the thermal event of Fig. 2a. The extinction of the spreading ridge system means the eventual dissipation of the thermally generated buoyancy force, ridge subsidence, and as the lithosphere mechanically recovers, the 'freezing-in' of the ridge topography by thermo-mechanical hysteresis.

The extinct spreading centre of the Coral Sea Basin (Fig. 4b) is associated with a short-wavelength (~ 50 km) free-air gravity anomaly low of 15–20 mGal and a longer-wavelength (~ 350 km) gravity high³⁰ (Fig. 4b). Since the rift valley topography has been buried by turbidites infilling the Coral Sea Basin from Australia and New Guinea, the source of the free-air gravity anomaly is approximately shared between the crust-sediment and crust-mantle interfaces. Calculating the gravity effect of each interface using the Bouguer approximation gives:

Interface (1): $42.2 \text{ mGal km}^{-1} \text{ g}^{-1} \text{ cm}^{-3}$

Upward continuation: $\exp(-kd)$; k , the wavenumber, is defined as $2\pi/L$, L being wavelength (~ 50 km) and, therefore, $k = 0.126$, and d , the mean depth of the interface, is ~ 5 km.

$$42.2(2.8 - 2.5)1.5 \exp(-0.126 \times 5) = 10 \text{ mGal}$$

Interface (2): $d = 10$ km, $k = 0.126$

$$42.2(3.33 - 2.8)1.5 \exp(-0.126 \times 10) = 9.5 \text{ mGal}$$

The combined free-air gravity effect is 19.5 mGal, indicating that the short-wavelength acoustic topography of the Coral Sea rift valley is conformable with the Moho topography. Given the accumulating evidence for the existence of an elastic layer supporting both active and inactive rifts³¹, it would appear that the 'frozen' ridge topography is most simply explained (though not explicitly modelled) in terms of the thermo-mechanical hysteresis of this elastic layer and is responsible for the observed crustal configuration and free-air gravity anomaly.

Ocean/continent boundaries

The final example relates to the persistent free-air gravity anomaly associated with ocean/continent boundaries, often highlighted by the calculation of an Airy isostatic anomaly, of many passive continental margins. The ocean/continent bound-

ary is characterized by a steep landward gradient, the midpoint of which identifies the position of the boundary as collaborated by magnetic anomalies and reflection seismics^{32,38,39}. Some margins also have an associated basement high which appears to be uncompensated³⁹. The form of the isostatic anomaly approximates a dipole, centred on the ocean/continent boundary, with the positive and negative components relating to the oceanic and continental sides respectively (Fig. 4c). A cause in terms of differential subsidence and flexure between the oceanic and continental crust is considered unlikely because, as noted by Watts and Steckler⁴⁰, the mechanical properties of thinned continental and oceanic lithosphere are similar and, therefore, it is not obvious why a flexural deformation between unstretched continental crust and thinned continental/oceanic crust should be centred on the ocean/continent boundary. In the case of the South China Sea (margin age ~ 30 Myr), the isostatic anomaly³² has an amplitude of ~ 30 mGal, ~ 400 km wavelength, and landward gradient $0.85 \text{ mGal km}^{-1}$ (Fig. 4c). In contrast, the significantly older Argentinian margin (age ~ 110 Myr) has an anomaly amplitude of ~ 60 mGal, 400 km wavelength, and gradient $0.95 \text{ mGal km}^{-1}$ (that is, the admittance tends to increase with increasing margin age). The steep gradient demands a relatively shallow source (crustal) while the wavelength and dipole nature of the anomaly suggests that compensation is related to the deformation of the crust. The association of this anomaly with a thermal process across the ocean/continent boundary (the initial continental rifting) again suggests that the ocean/continent boundary anomaly is a product of thermo-mechanical hysteresis.

Conclusions

Long after the cessation of inter- or intraplate thermal activity, the surface of the lithosphere will remain distorted with an amplitude and wavelength dependent on the mechanical properties of the lithosphere and the degree of reheating. This residual topography will remain indefinitely unless reset and hence redistributed by a subsequent thermal event. As the production of residual topography is a hysteresis process, the previous deformation is only replaced by a new deformation—the surface can never return to a stress-free state. Suitable thermal events include intraplate hotspots, formation of ridge topography at spreading centres, and continental (oceanic) rifting leading to the formation of an ocean/continent (ocean/ocean) boundary. Given the ability of the lithosphere to recover mechanically from a superimposed thermal event, the existence of TMH is an undeniable consequence. However, further work will be required to determine its exact importance.

I thank J. K. Weissel, J. F. Dewey, M. H. P. Bott, G. K. Westbrook, and M. S. Steckler for critically reviewing and improving the manuscript, M. D. Broussard and L. G. Karner for special assistance, and especially J. K. Weissel for supplying data relevant to the Cocos-Keeling trend. This work was supported by an Elf-Aquitaine Research Fellowship and the Society of Fellows, University of Durham.

The *c-myc* oncogene driven by immunoglobulin enhancers induces lymphoid malignancy in transgenic mice

Transgenic mice bearing the cellular myc oncogene coupled to the immunoglobulin μ or κ enhancer frequently develop a fatal lymphoma within a few months of birth. Since the tumours represent both immature and mature B lymphocytes, constitutive c-myc expression appears to be highly leukaemogenic at several stages of B-cell maturation. These myc mice should aid study of lymphoma development, B-cell ontogeny and immunoglobulin regulation.

THE arguments that a small number of cellular genes, the proto-oncogenes, are crucial to the development of neoplasia are persuasive^{1,2}. Nevertheless, the evidence that natural malignancies are caused by somatically altered proto-oncogenes has remained largely circumstantial³. Transgenic mice (reviewed in ref. 4) provide the means to test directly the efficacy of cellular oncogenes *in vivo*. Since a gene injected into a fertilized ovum typically integrates into a host chromosome within a few cell divisions, all tissues of the transgenic mouse usually acquire the gene, but the regulatory elements of the gene may direct tissue-specific expression⁴. Introduced immunoglobulin genes, for example, are expressed only in the lymphoid cells of transgenic mice⁵⁻⁸.

Recently, both a viral and a cellular oncogene have been shown to elicit characteristic tumours in transgenic mice. The type of tumour induced by the large-T antigen gene of simian virus 40 (SV40) depends on the element controlling its expression; with the SV40 enhancers, papillomas of the choroid plexus develop^{9,10}, while the insulin regulatory region leads to pancreatic tumours¹¹, and the metallothionein-I control region yields still other neoplasms¹². The cellular *myc* oncogene linked to the regulatory region within the long terminal repeat (LTR) of the mouse mammary tumour virus promotes mammary carcinomas¹³. These results suggest that tissue-specific regulators can target the action of oncogenes to particular cell types.

We wished to establish whether the *c-myc* gene can be introduced into the mouse genome in a form that promotes lymphoid malignancy. Altered regulation of *c-myc* expression has been strongly implicated in lymphoid neoplasia. In retrovirus-induced avian B lymphomas^{14,15} and some rodent T lymphomas^{16,17}, proviral insertion near *c-myc* brings it under the control of the promoter or enhancer within the retroviral LTR. In most human Burkitt's lymphomas and murine plasmacytomas, the *myc* gene has been activated by translocation to the immunoglobulin heavy (*IgH*)-chain locus (reviewed in refs 18-20). The way in which the *IgH* locus activates *c-myc* expression is poorly understood, but the lymphoid-specific *H* locus enhancer (*E μ*)²¹⁻²⁴ may well be the activating element in those translocations that couple it to *c-myc*.

By constructing transgenic mice bearing different forms of the *c-myc* gene, we have established that subjugation of this proto-oncogene to immunoglobulin enhancers converts it into a potent leukaemogenic agent for B lymphoid cells. Our results also support the notion that expression of the normal *myc* gene is subject to feedback regulation^{18,25} and bear upon the issue of whether an activated *c-myc* gene alone is sufficient to cause tumours. Since the predisposition is heritable, the novel lines of *myc* mice described here should prove valuable in unravelling early events in lymphoma development, in defining early stages

of lymphoid ontogeny, and in clarifying the mechanisms that regulate immunoglobulin gene expression.

Enhancers make *c-myc* tumorigenic

The seven constructs we have introduced into mice include an intact murine *c-myc* gene (top), a truncated form bearing the coding region (exons 2 and 3) and five versions with *c-myc* coupled to other regulatory regions (Fig. 1a). In the *E μ -myc* construct, which is equivalent to the rearranged *c-myc* allele in the plasmacytoma ABPC17 (ref. 26), the *H* locus enhancer lies upstream of exon 1, while in the LTR-*myc* construct the enhancer region of a murine retroviral LTR is positioned similarly¹⁶. In *E κ -SV-myc*, the lymphoid-specific immunoglobulin κ enhancer^{6,27,28} is coupled through the SV40 promoter to *myc* exons 2 and 3. SV-*myc* and MT-*myc* are analogous constructs containing the enhancer plus promoter of SV40 or the murine metallothionein-I gene, respectively. In four of the constructs the *myc* 3'-untranslated region was marked (Fig. 1b) with an irrelevant sequence (0.6 kilobases (kb) of Φ X174 phage DNA) to distinguish its transcripts from those of the endogenous *myc* gene.

To make transgenic *myc* mice, (C57BL \times SJL)F₂ eggs were injected with a construct, implanted in pseudopregnant females, and transgenic pups identified by hybridization to tail DNA²⁹. Many of these primary transgenic animals developed tumours, and the incidence is expressed in Fig. 1a as a fraction of the mice bearing each construct.

Significantly, both the μ and κ enhancer constructs elicited tumours and all involved lymphoid tissue. The *E μ -myc* gene was remarkably potent, 13 of 15 primary transgenic animals developing lymphomas (see below). These mice died, or became terminally ill (and hence were killed) between 6 and 15 weeks of age (median 11 weeks). With *E κ -SV-myc*, 6 of 17 transgenic animals died with lymphomas between 11 and 44 weeks of age (median 23 weeks). The efficacy and specificity of these constructs are almost certainly due to the immunoglobulin enhancers, because no tumours have arisen during 10 months of observation in the mice carrying either the tagged normal *myc* gene or the truncated form typical of most murine plasmacytomas^{19,20}. Since both immunoglobulin constructs were effective in multiple primary transgenic animals, each representing an independent insertion event, these enhancers must function in diverse chromosomal environments, as can intact μ and κ genes⁵⁻⁸.

The non-immunoglobulin constructs gave few tumours. The LTR enhancer-*myc* construct, which is derived from a T lymphoma¹⁶, gave rise to only one tumour, a thymic lymphoma. With the SV-*myc* construct, which is equivalent to one that transforms very effectively *in vitro*³⁰, 3 of 21 mice developed tumours: a lymphosarcoma, a renal carcinoma and a fibrosar-

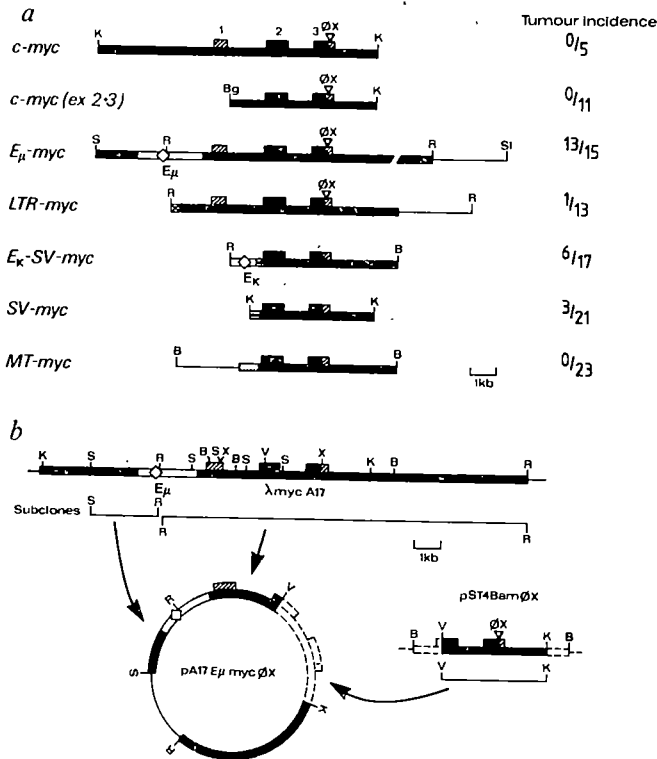

Fig. 1 **a**, The *c-myc* constructs injected into fertilized ova and tumour incidence in resulting transgenic mice. The solid bar denotes *c-myc* sequences with exons raised, untranslated regions striped, the ΦX174 marker DNA (see **b**) as a triangle, and vector sequences as a thin line. The linear fragments shown were isolated from plasmid constructs (described below) before injection. The *E_μ-myc* construct contains 2.3 kb of immunoglobulin DNA (open bar) spanning the H-chain enhancer (diamond), inserted 361 base pairs (bp) 5' to *c-myc* exon 1, as in plasmacytoma ABPC17 (see **b** and ref. 26) and extends 7.2 kb 3' to *c-myc*. The *LTR-myc* construct has the enhancer-containing 210 bp of the Soule murine leukaemia virus LTR (cross-hatched) inserted ~1.3 kb 5' to *c-myc*, as in T lymphoma ST4 (ref. 16). The bottom three constructs involve fusion to the *Xba*I site directly 5' to *myc* exon 2 (ref. 45). *E_κ-SV-myc* has an ~900-bp fragment of *κ* locus DNA (open bar) containing the *κ* enhancer (diamond) linked to the SV40 promoter (181-bp *Sph*I/*Stu*I fragment); *SV-myc* has the complete SV40 promoter/enhancer region (347-bp *Kpn*I/*Stu*I fragment); and *MT-myc* bears metallothionein-I sequences (stippled), from -750 to +6 (ref. 52), including its heavy metal-regulated promoter. **b**, Construction of *c-myc* plasmids. To mark the ABPC17 *c-myc* gene (ref. 26) within its 3'-untranslated region, the *Eco*RI fragment spanning *c-myc* was subcloned, and its *Eco*RV/*Kpn*I fragment exchanged for one bearing the ΦX174 marker. The latter was taken from pST4BamΦX, constructed by ligating a ΦX174 *Hae*III/*Xho*I fragment (nucleotides 4,984-162) via *Xho*I linkers to a *Xho*I-restricted *Bam*HI subclone isolated from the T lymphoma ST4 (ref. 16). Finally, the ΦX-marked *Eco*RI fragment was inserted at the *Eco*RI site of the ABPC17 *Sac*I/*Eco*RI subclone to give pA17E_μmycΦX. For injection, this plasmid was linearized with *Sal*II, which cuts within the pUC12 vector. The *c-myc* (ex 2+3) fragment was excised from pA17E_μmycΦX with *Bgl*III and *Kpn*I. The marked normal *c-myc* construct (**a**, top) was prepared analogously by replacing the 5' segment of pST4BamΦX (up to the unique *Eco*RV site in exon 2) with an 11-kb *Eco*RI/*Eco*RV fragment spanning the 5' end of the unrearranged *c-myc* gene; the 11.2-kb *Kpn*I fragment was then excised for injection. The *LTR-myc* plasmid was constructed by inserting the ΦX marker into an ~14-kb rearranged *c-myc* fragment from ST4 (ref. 16) by *Eco*RV/*Kpn*I exchange with pST4BamΦX as above, and the isolated *Eco*RI fragment injected. The *E_κ-SV-myc* plasmid was constructed by replacing the SV40 enhancer (*Sph*I/*Kpn*I) with a 900-bp fragment (nucleotides 3,390-4,290 in ref. 53) containing the *κ* enhancer. For *MT-myc*, the *Xba*I/*Bam*HI fragment spanning *myc* exons 2 and 3 was inserted into a MT vector containing a *Xba*I linker at +6 and a 3' *Bam*HI site; it was linearized at *Bam*HI for injection. Restriction endonuclease sites are: K, *Kpn*I; Bg, *Bgl*III; S, *Sac*I; R, *Eco*RI; Sl, *Sal*II; B, *Bam*HI; X, *Xho*I; V, *Eco*RV.

coma. This diversity echoes the wide range of cells in which the SV40 enhancer functions. The absence of tumours of the choroid plexus with this construct may mean that the *myc* gene product is less effective than the large-T antigen^{9,10} in transforming brain epithelial cells. We were surprised that no tumours ensued with the MT-*myc* construct, because that control region has induced expression of other genes in transgenic mice^{12,31,32}, but the vector sequences present in this construct (Fig. 1a) may have had a suppressive effect³³.

Aggressive lymphoma

The striking efficacy of the *E_μ-myc* construct led us to concentrate on mice bearing it. To establish whether the predisposition to lymphoma development was heritable, we analysed progeny from primary *E_μ-myc* mice that survived long enough to allow breeding. In eight independent lineages, lymphomas have developed with high fidelity. Indeed, in three generations of descendants, 59 of 63 mice (94%) have died by 4 months of age. The pathology is very similar in all lineages.

The hallmark of the disease in *E_μ-myc* mice is massive enlargement of the lymph nodes. The onset, most readily assessed by palpation of the inguinal lymph nodes, usually occurs between 3 and 18 weeks of age. A few weeks later, most mice develop 'water wings', prominent lumps on both shoulders and the neck (Fig. 2a), reflecting swelling of the brachial and cervical lymph nodes, and most other nodes are grossly enlarged (Fig. 2b). The spleen usually shows modest (about twofold) expansion and the thymus is markedly enlarged in some mice. The enlarged lymphoid organs are replete with lymphoblasts and the blood contains large numbers of similar cells. Variable invasion of other tissues is often observed. The typical pathological diagnosis is therefore multicentric lymphosarcoma (disseminated lymphoma) with associated leukaemia. Occasionally, mice have developed a thymoma without notable involvement of peripheral lymphoid organs and some have succumbed to a bowel obstruction caused by intestinal involution (intussusception) over focal growths of lymphoblasts in the wall. The typical pathology is somewhat like that induced by Abelson murine leukaemia virus³⁴.

Transplantation into syngeneic mice established that the enlarged lymphoid organs of *E_μ-myc* mice represented frank tumours rather than massive proliferations of 'normal' cells. Rapidly growing tumours arose in the (C57×SJL)F₁ hybrid recipients a few weeks after injection of 10⁵-10⁶ cells from each of 10 *E_μ-myc* mice, including all those in Table 1. Indeed, 10² cells from one tumour tested at lower cell numbers (4Met in Table 1) initiated tumours within 2-3 weeks. The disease in *E_μ-myc* mice is patently highly malignant.

Tumours from single B-lymphoid clones

We wished to identify the cell lineage(s) from which the tumours were derived. The pathology was highly suggestive of a lymphoid disease but did not rule out myeloid involvement. Transcriptional studies of the *μ* constant-region (*C_μ*) locus³⁵⁻³⁷ and gene transfer studies^{7,24} suggest that *E_μ* can operate in many T lymphocytes and certain other haematopoietic cells as well as B cells, but all the tumours so far analysed in detail are B lymphoid in origin. All cell lines derived from them are non-adherent and have an absolute requirement for 2-mercaptoethanol, a strong indication of lymphoid rather than myeloid origin. As expected for B cells, all tumours and cell lines displayed rearrangement and expression of the *IgH* and/or *κ* loci, as illustrated in Figs 3 and 4 and summarized in Table 1 for the tumours of five mice. Arguing against a T-cell origin, no tumour so far studied has displayed the Thy-1 surface antigen, nor exhibited rearrangement or transcription of the T-cell antigen receptor *β* locus (data not shown). Moreover, since the *κ* locus (unlike the *H* locus) appears to be transcriptionally silent in T lymphocytes (refs 6, 38 and our unpublished results), the presence of *κ*-locus transcripts in all the *E_μ-myc* tumour cell lines (see below) strongly favours a B-lymphoid origin.

Table 1 Representative tumours arising in E_{μ} -myc transgenic mice

Pathology	Cell line	Ig genes [‡]		Ig RNA [‡]		sIg #		Cell type
		H	κ	H	κ	1°	2°	
Mouse 1 (285-5-6)♂ Multicentric lymphoma/leukaemia with very large pancreatic lymph node	1 Pan*	R1, R2	G	C_{μ} ++	κ^0+	0	0	Pre-B clone A
	1 Bra*	R3	G	C_{μ} ++	κ^0+	0	0	Pre-B clone B
Mouse 2 (285-5-12)♀ Multicentric lymphoma/leukaemia with thymoma	2 Thy†	R1, R2	G	C_{μ} ++	κ^0+	0	0	Pre-B clone A
	2 Bra*	R3, G§	G	C_{μ} ++	κ^0+	ND	0	Pre-B clone B
	2AxL	R3, G§	G	C_{μ} ++	κ^0+	0	0	Pre-B clone B
	2 Mes*	R3, G§	ND	C_{μ} ++	κ^0+	ND	<5	Pre-B clone B
Mouse 3 (285-5-9)♀ Multicentric lymphoma/leukaemia with intussusception of intestine	3 Mes	R1, R2	R1	μ ++	κ ++	5-10	>90	Pre-B → B clone A
	3 Bra	R1, R2	G	μ ++	κ^0+	5-10	10**	Pre-B → B clone A
Mouse 4 (292-5-5)♂ Multicentric lymphoma/leukaemia with enlarged thymus	4 Thy†	R1, R2	R1, R2	(μ , C_{μ})+++	κ +++	80-90	>90	B clone A
	4 Mes†	R3, R4	R3, R4	(μ , C_{μ})+++	κ +++	80-90	>90	B clone B
	4 Bra†	R3, R4	ND	(μ , C_{μ})+++	κ +++	80-90	>90	B clone B
	4 Met†	R3, R4	ND	(μ , C_{μ})+++	κ +++	80-90	>90	B clone B
Mouse 7 (292-1-1-11)♂ Multicentric lymphoma/leukaemia with thymoma and lymphoblast infiltration of perinodal fat	7 Mes*	R1, R2	R	C_{μ} ++	κ ++	0	0	Pre-B clone A
	7 BM	R1, R2	R	C_{μ} ++	κ ++	ND	ND	Pre-B clone A
	7 ThyD*	R1, R2	R	C_{μ} ++	κ ++	0	ND	Pre-B clone A
	7 ThyV*	R1, R2	R	C_{μ} ++	ND	ND	ND	Pre-B clone A
	7 Spl*	R1, R2	R	C_{μ} ++	ND	ND	ND	Pre-B clone A

Mice specified here were first- or second-generation descendants of three primary transgenic mice (285-5, 292-5 and 292-1) bred with normal (C57BL × SJL)_{F1} hybrids. Sick mice killed by exsanguination under anaesthesia were dissected for assessment of gross pathology. Tissue sections were stained with haematoxylin and eosin and blood smears stained with Giemsa for histopathological assessment. Cell lines are designated by their origin as tumours in the pancreatic (Pan), brachial (Bra), axillary (AxL), mesenteric (Mes) lymph nodes; diffuse mediastinal tissue (Met), thymus (Thy), spleen (Spl) or bone marrow (BM). ThyD and ThyV derived from discrete masses situated dorsally and ventrally in the position of normal thymus. ND, not determined.

* Primary tumour and cell line shown to have equivalent J_H rearrangements.

† Primary tumour oligoclonal but dominated by the single clone present in cell line.

‡ Rearrangement of J_H alleles was determined by Southern blot analysis of *Eco*RI digests using ³²P-labelled probe A (Fig. 3), while J_{κ} analysis used *Bam*HI digests and probe C (Fig. 4, top). G indicates a fragment the same size as that in germline (liver) DNA from C57BL or SJL mice, while R1-R4 indicate rearranged fragments of different sizes.

§ Other rearranged J_H fragments were present in minor yield. We are investigating whether the fragment in germline position is truly unrearranged.

|| Four rearranged bands were detected and their relationship to each other is under investigation.

μ and κ denote authentic μ and κ mRNA, while C_{μ} denotes all other C_{μ} -bearing RNA species (see refs 35, 37, 39) and κ^0 denotes transcripts of the unrearranged κ locus (see Fig. 4). +++ indicates a level comparable to that in a conventional B lymphoma (WEHI-231), and ++ and + about one-third and one-tenth that level.

% Cells with surface immunoglobulin (sIg) in either the primary tumour (1°) or the cell line derived from it (2°).

** Growth used for RNA and DNA analysis was 10% sIg⁺, but the line subsequently progressed to >90% sIg⁺.

Although E_{μ} -driven *myc* expression might be expected to trigger proliferation of the entire B-cell compartment, the simplicity of the *IgH* locus rearrangement patterns (Fig. 3) provided strong evidence that most tumours are monoclonal. Most contain two fragments bearing a heavy-chain joining region (J_H) in equimolar yield but lack the 6.5-kb 'germline' fragment found in liver (G), precisely as expected for a clonal lymphoid cell line that has undergone diversity-joining region (DJ) or variable-diversity-joining region (VDJ) recombination at both *IgH* alleles. The apparent single rearranged fragment in tumours such as 1BraC probably reflects two co-migrating fragments. While a few primary tumours (for example, 2AxL, Table 1) contained four to six rearranged J_H fragments, indicative of oligoclonality, one or two bands always strongly predominated.

The J_H rearrangement pattern also confirmed that the cultured line (C) represented either the sole or very dominant clone within the primary tumour (T) mass (compare C and T for several tumours in Fig. 3).

The tumour masses at different sites in a *myc* mouse are frequently derived from the same clone. In mouse 7, for example, tumours from five different sites displayed identical J_H rearrangements (Fig. 3, Table 1) and even the liver had been invaded by this clone (Fig. 3). Some mice, however, appeared to bear more than one independent tumour (Table 1). For example, the pancreatic and brachial lymph node tumours in mouse 1 (1Pan and 1Bra) had different J_H rearrangements, while the thymic tumours in mice 2 and 4 differed from the lymph node tumours (Fig. 3). These differences may reflect independent transformation events, or maturation of a single primary clone by further rearrangement, such as recombination of V with DJ segments.

B-lymphocyte transformation

The pre-B cell, the earliest defined stage in B-cell ontogeny, displays rearrangement at the heavy-chain locus (*DJ* or *VDJ*) but lacks surface immunoglobulin (sIg), usually because the κ or λ light chain loci are unrearranged. Fusion of a V_{κ} gene with J_{κ} (or, more rarely, V_{λ} with J_{λ}) permits κ or λ expression and progression to the mature (sIg⁺) B cell. Although *c-myc* has been implicated only in tumours of mature B cells and plasma cells, the E_{μ} -*myc* tumours include some with pre-B characteristics, others that represent mature B cells and one that progressed from the pre-B to the B-cell stage (Table 1). Hence, *myc*-induced tumorigenesis is not stage-specific.

Tumours of pre-B type developed in mice 1, 2 and 7 (Table 1). No sIg was present, and μ_m messenger RNA, which encodes the membrane form of μ -chain, was not detected by blot

Fig. 2 a, Fourth-generation E_{μ} -*myc* mouse, 11 weeks old, with swellings due to grossly enlarged lymph nodes. b, Interior of same mouse, displaying gross bilateral enlargement of (from the top) cervical, axillary, brachial, mesenteric and inguinal lymph nodes.

Fig. 3 Rearrangement at the immunoglobulin heavy-chain locus in tumours arising in E_{μ} -myc mice. The diagram indicates the structure of the J_H - C_{μ} locus before rearrangement (germline configuration), with exons indicated as solid boxes, and the enhancer (E_{μ}) as a diamond. Hatched area is the region inserted 5' to c -myc in the E_{μ} -myc construct, and Eco RI (R), Bam HI (B) and $Hind$ III sites are shown. The Southern blot shows J_H rearrangements revealed in Eco RI-cut DNA by hybridization with 32 P-labelled probe A, a 450-bp $Hind$ III/ Nae I fragment, subcloned to eliminate sequences within the E_{μ} -myc insert. An additional fragment detected by probe A in 4Thy (and weakly in 4Mes) is too small (2.8 kb) to be shown by this autoradiograph. An arrow marks the position of the unrearranged J_H -bearing fragment (G) and sizes of marker fragments are given in kilobase pairs (kb). Probe B, a 1.5-kb Eco RI/ Hha I fragment, is the S_{μ} probe used in Fig. 5.

hybridization with a C_{μ} probe (Table 1). As will be documented elsewhere, the C_{μ} -bearing RNAs in these lines are those expected³⁵⁻⁴¹ from either partially rearranged (DJ_H) or unrearranged heavy-chain locus alleles. The tumour in mouse 7 is of an unusual pre-B type, having a κ rearrangement and κ mRNA without μ_m mRNA (Table 1).

Although the cell lines from mice 1 and 2 lack κ rearrangement (Table 1), we found not only the known 8-kb transcript of the germline C_{κ} locus⁴², which initiates upstream of J_{κ} (Fig. 4, top), and a 0.8-kb species⁴³, but also an ~1.1-kb species, the size of κ mRNA (Fig. 4a). Unlike κ mRNA, however, this species bears sequences upstream of J_{κ} , since it hybridizes with probe A + B (Fig. 4b) and probe A alone (not shown). We therefore suggest that processing of the 8-kb RNA generates this previously unrecognized⁴² κ RNA species (Fig. 4, top).

An intriguing tumour that progressed from a pre-B to a B cell developed in mouse 3. The J_H rearrangement patterns assign its mesenteric and brachial lymph node tumours (3Mes and 3Bra) to the same clone (Fig. 3), but only 3Mes had a J_{κ} rearrangement (Table 1). However, after only a few weeks in culture, over 90% of 3Mes cells became sIg⁺, as later occurred for 3Bra. We conclude that this leukaemic pre-B clone generates mature B-cell progeny, as can a few lymphomas induced by Abelson murine leukaemia virus⁴⁴. Thus a c -myc-induced tumour need not be 'frozen' at one stage of differentiation.

Expression of myc gene

Abundant c -myc mRNA was detected in all the E_{μ} -myc cell lines examined, as illustrated for six lines in Fig. 5a. The levels in all the lines, which included tumours from three separate E_{μ} -myc lineages, were comparable and fell within the upper range of that we have observed in plasmacytomas^{45,46}. Due to the 0.6-kb Φ X174 insert within the myc 3' untranslated region (Fig. 1), all the lines contained an ~3-kb myc mRNA, which also hybridized to the appropriate Φ X174 probe (not shown), whereas a normal, unrearranged myc gene yields ~2.3-kb transcripts, as shown for plasmacytoma ABPC103 and B lymphoma WEHI-231 in Fig. 5a. Significantly, no normal c -myc mRNA was detectable in any E_{μ} -myc cell line, even after lengthy autoradiographic exposures (for example, Fig. 5b). Moreover, treatment of four of the lines with the B-cell mitogen lipopolysaccharide (LPS) at 20 μ g ml⁻¹ for 24 or 48 h did not induce normal

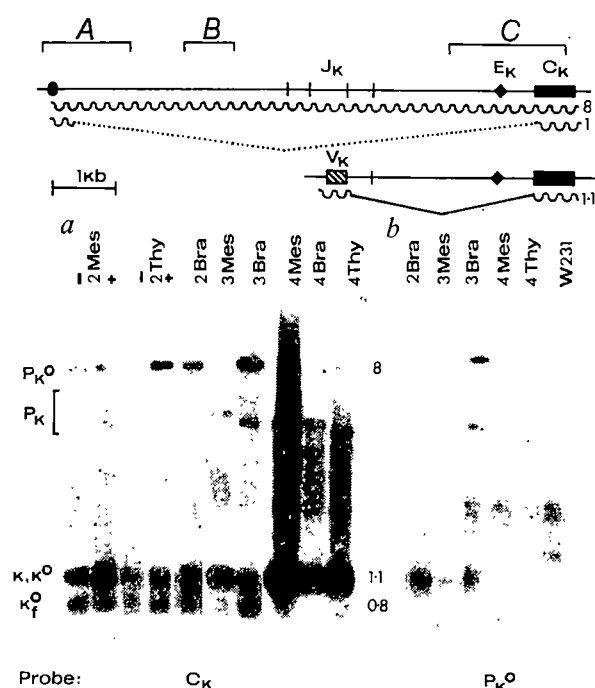

Fig. 4 Transcripts of the κ locus in lymphoma cell lines from E_{μ} -myc mice. The diagram shows that transcripts from the germline C_{κ} locus (top) include a previously described⁴² 8-kb unprocessed (nuclear) RNA initiated at a promoter (filled circle) 3.2 kb upstream from J_{κ} and a proposed spliced ~1.1-kb product (κ) derived from it (see text), while an assembled $V_{\kappa}J_{\kappa}C_{\kappa}$ gene yields 1.1-kb κ mRNA. *a*, C_{κ} -bearing transcripts in the tumour lines. + and - denote cultures grown for 24-48 h in the presence (+) or absence (-) of 20 μ g ml⁻¹ bacterial LPS. The C_{κ} probe was probe C (top), a subcloned 1.5-kb $Hind$ III/ Bgl II fragment. κ_i^0 denotes a 0.8-kb C_{κ} -bearing transcript proposed to be derived from a germline allele (see text), while P_{κ}^0 denotes the unprocessed precursor of authentic κ mRNA. *b*, Transcripts revealed with upstream probes (a mixture of probes A + B above), showing that an ~1.1-kb poly(A)⁺ RNA bears upstream sequences. Probe A alone also labelled the 1.1- and 8-kb species. Probe A is a 1.4-kb $Hind$ III/ Xba I fragment and probe B a 0.7-kb $Hind$ III fragment (see Fig. 1 in ref. 42), prepared from a 12.7-kb Bam HI clone kindly provided by M. Weigert. These probes are free of C_{κ} sequences because they did not reveal a 1.1-kb species in WEHI-231 (W231), which contains abundant κ mRNA, nor in several plasmacytoma lines in which both alleles are rearranged (not shown).

Methods. Tumour lines were established in Dulbecco's modified Eagle's medium supplemented with 50 μ M 2-mercaptoethanol, 100 μ M asparagine and 10% fetal calf serum. Within a few weeks of initiation into culture, the cells were grown in roller bottles and collected while in exponential growth phase ($1-2 \times 10^6$ cells ml⁻¹). Poly(A)⁺ total cellular RNA was isolated from ~10⁹ cells by a method⁵⁴ involving digestion with proteinase K and oligo-dT cellulose chromatography. RNA (2 μ g) heated for 5 min at 65 °C in buffered 2 M formaldehyde/50% formamide was fractionated electrophoretically on a 1.2% agarose/2 M formaldehyde gel and blotted on to nitrocellulose⁵⁵. Hybridization was carried out overnight in 50% formamide/5 \times SSC (SSC is 0.15 M NaCl, 15 mM sodium citrate, pH 7.0) at 42 °C, and washing in 2 \times SSC at 65 °C.

c -myc transcripts (or alter E_{μ} -myc expression), although shorter times might be needed to reveal the c -myc stimulation observed in normal B cells⁴⁷. At least three of the cell lines were clearly responsive to LPS, since their growth rate increased and the levels of some immunoglobulin RNAs increased slightly (Fig. 4 and our unpublished results). The absence of normal c -myc transcripts favours a feedback control model for myc expression (see below).

Two classes of myc RNA of similar size are apparently made from the E_{μ} -myc insert (Fig. 5, top). One class bears myc exon 1 sequences (Fig. 5c) and appears to initiate at the normal myc promoters P_1 and P_2 , judging by S_1 nuclease protection results (W.A., unpublished results). The second class, apparently of

Fig. 5 Transcripts of the *myc* gene in lymphoma cell lines from E_{μ} -*myc* mice. Proposed transcripts from the E_{μ} -*myc* insert are shown at the top (see text). *a*, *myc* transcripts in transgenic lines showing absence of the normal ~2.3-kb *myc* mRNA present in ABPC103 (A103) and WEHI-231, whether the cells were treated with LPS (+) or untreated (-). *b*, Longer exposure of two lanes from *a* (3 days rather than 8 h). *c*, Transcripts bearing exon 1 sequences. *d*, Transcripts bearing S_{μ} sequences, indicating the proposed S_{μ} -(*myc* exons 2+3)-hybrid RNA (S_{μ} -*myc*). The *myc* 2+3 probe was a 1.7-kb *Xho*I fragment from a murine *myc* complementary DNA clone kindly provided by K. Marcu; *myc* ex 1, a *Bam*HI/*Xho*I fragment from exon 1 (see map in ref. 45); S_{μ} , a unique-sequence 1.5-kb *Eco*RI/*Hha*I fragment indicated as bar *B* in Fig. 3 (top).

comparable abundance, may have a 5' segment equivalent to that on certain ' S_{μ} ' RNAs, which bear sequences extending ~0.7 kb downstream from E_{μ} , spliced to C_{μ} (ref. 39). A μ switch region (S_{μ})-*myc* hybrid transcript would explain the novel ~3.0-kb RNA species that hybridizes in all the tumour lines to an S_{μ} probe (Fig. 5*d*) but not to a C_{μ} probe (data not shown). Splicing of the ~0.7-kb S_{μ} sequence to *myc* exon 2 (where the first known splice acceptor occurs), would yield a *myc* RNA marginally larger than the species bearing the normal 0.55-kb *myc* exon 1 (3.2 kb compared with 3.0 kb) and indeed the S_{μ} -bearing species is slightly larger than that detected by a *myc* exon 1 probe on the same filter. The S_{μ} -*myc* RNA is unlikely to encode an altered *myc* polypeptide, because all the ATG sequences within the relevant segment of S_{μ} are followed shortly by stop codons.

Discussion

The novel lymphoid neoplasia described here demonstrates dramatically that subgenation of *c-myc* expression to the immunoglobulin μ or κ enhancer converts this proto-oncogene into a potent leukaemogenic agent *in vivo*. Presumably the malignancy is a consequence of high constitutive *myc* expression within the lymphoid compartment, forced by these enhancers, which are activated by lymphoid factors^{21-23,27,28}. In primary transgenic animals, the E_{μ} -*myc* and E_{κ} -SV-*myc* constructs induced an equivalent pathology, but the E_{μ} -*myc* gene gave a higher tumour incidence and somewhat shorter latent period. This might reflect the greater enhancer activity of E_{μ} over E_{κ} with certain promoters²⁸, or a larger pool of susceptible cells, since E_{μ} is probably activated earlier in lymphoid ontogeny than E_{κ} .

The predisposition to neoplasia in the transgenic lines of E_{μ} -*myc* mice is nearly absolute: over four generations, more than 100 mice involving eight lineages have succumbed within a few months of birth. The typical disease is an aggressive multifocal lymphoma/leukaemia involving lymphoid organs, including the bone marrow, and often invading other tissues. To date, all tumours studied in detail are of the B-lymphoid lineage, but the indications that the E_{μ} enhancer is also active in other haematopoietic cells^{7,35,36,38} leave open the possibility that malignancies of T lymphocytes and myeloid cells arise at a lower frequency. The induction of tumours representing pre-B as well as B cells indicates that *myc*-promoted tumorigenicity is not restricted to one stage.

Our observation that the normal endogenous *myc* genes of the E_{μ} -*myc* tumour lines are silent (Fig. 5) is highly reminiscent

of findings regarding *myc* translocations¹⁸⁻²⁰: in almost all murine plasmacytomas and Burkitt's lymphomas, only the translocated *myc* allele is active^{45,46,48}. One model to account for such results proposes that the normal *myc* gene is subject to negative feedback control by an excess of the *myc* polypeptide or products induced by it^{18,25}. Translocation to the *IgH* locus, or the influence of the E_{μ} enhancer, frees that *c-myc* gene from this restraint, and the ensuing constitutive *myc* expression silences the unaltered allele(s). An alternative model suggests that *c-myc* would not be expressed in a normal cell at the stage of B-cell maturation equivalent to the tumour^{19,49}. A corollary of this model is that *c-myc* expression should be tumorigenic only at those stages where it is normally silent. Judging from Burkitt's lymphomas and murine plasmacytomas, the susceptible stage(s) would be relatively late in B-cell ontogeny, either sIg^{+} B cells or plasma cells. Our evidence that *c-myc* can participate in the transformation of pre-B cells as well as mature B cells argues against this model but is consistent with feedback control.

It has been possible to argue that the major effect of most *myc* translocations is to dissociate the coding region from a negative regulatory element within *myc* exon 1 or its 5'-flanking region, the immunoglobulin locus being merely a passive bystander caught up because of its propensity for rearrangement (see refs 18-20). We found, however, that a *myc* construct lacking the entire 5' portion but bearing all the cryptic promoters within intron 1 (*myc* ex 2+3 in Fig. 1) was completely ineffectual *in vivo*, as was the intact *myc* gene, in marked contrast to the E_{μ} and E_{κ} constructs. These results bolster the case that the immunoglobulin loci have a positive regulatory input. The puzzle that only a minority of *myc* translocations leave *myc* and E_{μ} on the same chromosome may be partially resolved by evidence that *IgH* genes remain active *in vivo* even when deletions remove E_{μ} (ref. 50). If E_{μ} is needed to initiate but not maintain an active chromatin configuration within the C_H locus, the active C_H locus may suffice for *myc* activation.

A critical issue in oncology is whether a single oncogene can shift a normal cell to the fully malignant state. The potency *in vivo* of the acute retroviruses, such as those bearing *v-myc*, seems to argue that one oncogene suffices, but *in vitro* studies suggest that transformation of normal cells usually requires particular combinations of active oncogenes, such as a *myc* plus a *ras* gene³⁰. The nearly invariant leukaemogenesis of E_{μ} -*myc* mice might be taken as evidence that an active *myc* gene is sufficient for lymphoid neoplasia, but several observations make us think that other events (presumably genetic) influence tumour development. First, the latent period before any overt signs arise is variable and can be as long as 5 months, whereas we would expect E_{μ} -driven *myc* expression to commence concomitantly with B-cell ontogeny, well before birth. Second, there appears to be a true pre-neoplastic state in these mice, since no malignant cells, as assessed by transplantation, are detectable within the lymphoid organs of young transgenic mice free of overt disease (A.W.H., unpublished results). Finally, we are struck by the fact that many of the tumours are monoclonal (Table 1). Since the E_{μ} -*myc* gene should be active within the entire B-lymphoid compartment, clonality implies that one lymphocyte acquired a decided growth advantage, probably by some still undefined genetic alteration. Conceivably the background of the mice (C57BL \times SJL) F_2 might also have some role, since aged SJL mice are subject to a neoplastic disorder of the lympho-reticular system⁵¹.

If dysregulated *c-myc* expression is insufficient for malignancy, why does it elicit high-frequency tumorigenesis? *myc* expression is normally associated with dividing cells and drops precipitously as the cell enters the resting (G_0) state¹⁸⁻²⁰. Thus, constitutive *myc* expression above a certain threshold may promote cell division at the expense of differentiation. The probability that a given cell will proliferate (self-renew) rather than generate differentiated progeny may be set by the level of *c-myc*, or a balance between *myc* and differentiation-promoting elements. This model predicts that excess *myc* expression in a given

lineage will increase the proportion of cells that are less mature and therefore have greater proliferative capacity. Any accidental event that further increases the proliferation/differentiation ratio in a member of this large vulnerable population then creates the malignant clone.

It already seems clear that the diverse set of B-lymphoid cell lines generated by E_{μ} -myc mice will aid studies on lymphoid ontogeny and the mechanisms that regulate immunoglobulin gene rearrangement and expression. Even more significant, the very high predisposition of these mice to neoplasia provides new opportunities for exploring the pre-neoplastic state. It will be intriguing to discover in what ways the haematopoietic popu-

lations have been perturbed by this cellular oncogene freed from its normal restraints.

The Torpedo and calf acetylcholine receptors and hybrids composed of subunits from the two species have been produced in Xenopus oocytes by the use of the cloned complementary DNAs. Single-channel current measurements indicate that these receptors form channels of similar conductance but with different gating behaviour.

THE nicotinic acetylcholine receptor (AChR) is a transmembrane protein constituting a ligand-gated ionic channel. In the absence of acetylcholine (ACh), the channel is in the closed state. When ACh is bound to the receptor, the channel opens for a few milliseconds, giving rise to an elementary current pulse¹, the size and duration of which can be observed directly by the patch-clamp technique². Biochemical evidence has shown that the AChR from *Torpedo* electroplax consists of four kinds of homologous subunits assembled in a molar stoichiometry of $\alpha_2\beta\gamma\delta$ and that the α -subunit carries the ACh-binding site³⁻⁵. The primary structures of all four subunits of the *Torpedo* electroplax⁶⁻¹¹ and mammalian muscle AChRs¹²⁻¹⁷, the γ - and δ -subunits of the avian AChR¹⁸ and the newly found ϵ -subunit of the calf muscle AChR¹⁹ have been elucidated by cloning and

sequencing complementary DNAs or genomic DNAs encoding these polypeptides. The cloned cDNAs encoding the α -, β -, γ - and δ -subunits of the *Torpedo* AChR can be expressed to produce the functional receptor in *Xenopus* oocytes^{20,21} and analysis of the functional properties of AChR mutants possessing α -subunits altered by site-directed mutagenesis of the cDNA has enabled functional regions of the subunit molecule to be localized²¹.

One possible approach to studying the functional roles of the individual subunits in ion transport and gating of the AChR channel would be to construct hybrid AChR molecules using subunits from different species and to compare their channel properties with those of the parental AChRs. It has been shown recently that the hybrid AChRs composed of the *Torpedo* α -,

Xenopus laevis oocytes were injected with various combinations of *Torpedo* (indicated by the suffix T) and calf (indicated by the suffix C) AChR subunit-specific mRNAs as specified; molar ratio of the α -, β -, γ - and δ -subunit-specific mRNAs, 2:1:1:1; total mRNA concentration, 100–140 ng μ l⁻¹; average volume injected per oocyte, 20–50 nl. The oocytes were incubated for 2–4 days in conditions described previously²⁰ before being tested for α -BTX binding activity or response to ACh. Data are given as means \pm s.d. Numbers in parentheses refer to the number of experiments for α -BTX binding activity (pools of 10–20 oocytes used in each experiment) or the number of oocytes or membrane patches for current measurements. For assay of the toxin-binding activity on the cell surface³², intact oocytes were incubated at room temperature for 3 h with 2 nM ¹²⁵I- α -BTX (213 Ci mmol⁻¹) in modified Barth's medium³⁴ containing 1 mg ml⁻¹ bovine serum albumin. The toxin-binding activity in cell extracts was determined by the antibody precipitation assay as described previously^{20,21}, using the monoclonal antibody reactive with the calf AChR (mAb210) for oocytes injected with the subunit-specific mRNA combination $\alpha_C\beta_C\gamma_C\delta_C$ or $\alpha_C\beta_T\gamma_T\delta_T$, or rabbit antiserum to the *T. californica* AChR for oocytes injected with the other mRNA combinations; incubation was at room temperature for 3 h in the presence of 2 nM ¹²⁵I- α -BTX. AChR channel activity represents membrane currents in response to bath application of 0.1 μ M ACh. The membrane potential was voltage-clamped at -70 mV. Oocytes injected with the subunit-specific mRNA combination $\alpha_T\beta_C\gamma_T\delta_T$ or $\alpha_T\beta_T\gamma_C\delta_T$ did not respond to 0.1 μ M ACh, but they responded to 0.5 μ M ACh, the average channel activity being 18 \pm 22 nA(7) and 5 \pm 3 nA(3), respectively. Reversal potentials were determined as described in Fig. 1 legend. The voltage sensitivity was quantified as the ratio of the slope conductances at -100 mV and 0 mV membrane potential, measured in Ringer's solution with 1.0 mM or 1.8 mM Mg²⁺ replacing Ca²⁺ (ref. 21). Conductance values represent slope conductances. Mean current amplitudes were measured at least at three different membrane potentials, ranging from -120 mV to -20 mV, in each experiment. The single-channel conductance was obtained as the slope of the *i*-*V* relation determined by linear regression. The average durations of single channel currents are defined as follows. Single-channel current burst durations were measured as any sequence of events separated by less than a critical closed interval of 1 ms. The distributions of such bursts were fitted satisfactorily only by the sum of two exponential components, except for some measurements of the *Torpedo* AChR (see text). The average current durations given represent the slower component. In all cases, the slower component represented more than 70% of the area of the distribution. Averages are from experiments at -110 mV to -70 mV membrane potential.

* Mean of 2.8 and 3.4; † mean of 1.45 and 1.78; ‡ mean of 1.55 and 1.94.

β - and δ -subunits and either the calf γ - or ϵ -subunit are functional when expressed in *Xenopus* oocytes¹⁹. Here we report conductance and gating properties of the *Torpedo* and calf AChRs as well as of the hybrid AChRs in which the α - or δ -subunit of the *Torpedo* AChR is replaced by the corresponding subunit of the calf AChR. Substitution of the calf δ -subunit in the *Torpedo* AChR alters the gating behaviour of the channel drastically, making it similar to the calf AChR channel. Substitution of the calf α -subunit has less effect on the gating properties of the *Torpedo* AChR channel. The conductance of the channel is not significantly affected by either substitution.

Torpedo and calf AChR channels

Activity of AChR channels in oocytes. The mRNAs specific for the α -, β -, γ - and δ -subunits of the *Torpedo californica* electroplax and calf muscle AChRs were synthesized *in vitro*^{22,23} using the respective cDNA templates (see refs 19, 21 and Fig. 1 legend). The four subunit-specific mRNAs for the *Torpedo* or calf AChR were combined and introduced into *Xenopus* oocytes by microinjection. The oocytes injected with the calf mRNAs responded to ACh much more strongly than did the oocytes injected with the *Torpedo* mRNAs (Fig. 1a, b), the average membrane currents activated by 0.1 μ M ACh being 1,600 nA and 23 nA, respectively (Table 1). This large difference in membrane current cannot be accounted for by different densities of the calf and *Torpedo* AChRs expressed in the oocyte membrane because the binding activity of α -bungarotoxin (α -BTX) on the cell surface did not differ significantly between the two groups of oocytes (Table 1). These observations imply some functional differences between the calf and *Torpedo* AChR channels.

The current through a membrane (I_m) is given by $I_m = n i p(o)$, where n represents the number of channels, i the current through a single channel at a given membrane voltage, and $p(o)$ the probability of the channel being open. Because it can be assumed that the number of channels does not vary significantly between the two groups of oocytes, the difference in channel activity

could reflect a larger elementary current flowing through a single calf AChR channel, or it could reflect a higher open probability of the channel at the given ACh concentration. The following whole-cell and single-channel current measurements were designed to decide between these possibilities.

Figure 1c, d shows current-voltage (*I*-*V*) relations of the ACh-activated current determined in oocytes injected with either the four *Torpedo* or the four calf subunit-specific mRNAs. The reversal potential of the ACh-activated current was -11 to -4 mV in both groups of oocytes (Table 1), suggesting that both the *Torpedo* and the calf AChR channels have similar ion selectivity. A marked difference was observed, however, in the shape of the *I*-*V* relation. In oocytes implanted with the *Torpedo* AChR, the *I*-*V* relation was almost linear, but was curved for oocytes implanted with the calf AChR, indicating an inward rectifying conductance similar to that of frog endplate channels^{24,25}.

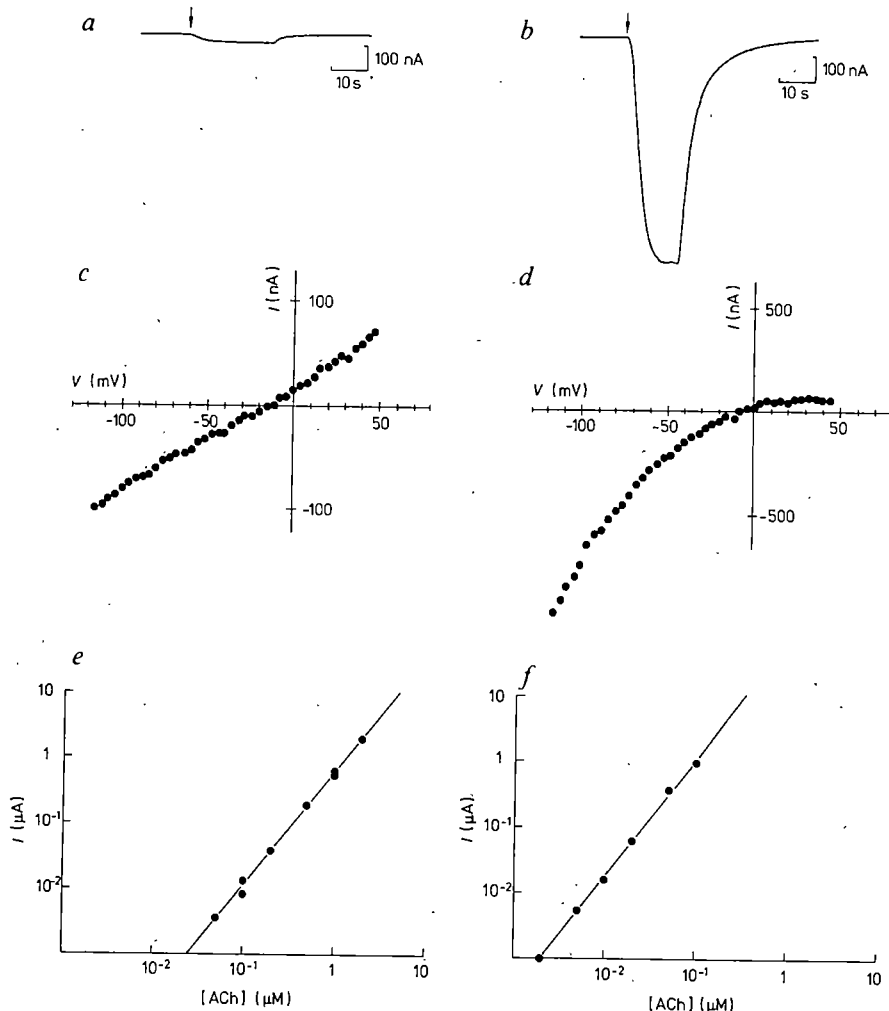

The relation between ACh concentration and membrane current was supralinear, with a Hill coefficient of 1.6–1.7 for both groups of oocytes (Fig. 1e, f, Table 1). This indicates that the *Torpedo* and calf AChRs are comparable in stoichiometry of ACh binding and that the large difference in oocyte channel activity is probably not due to a difference in agonist-receptor stoichiometry. A plausible reaction mechanism for the opening of AChR channels in muscle assumes that channel opening occurs from the bi-liganded receptor²⁶. The agonist-receptor interaction is described by

where R is the resting receptor, A_1R and A_2R are the mono-liganded and bi-liganded receptors, respectively, and the asterisk indicates the open channel state. This simplified reaction scheme does not take other reaction pathways into account. However, it can describe the supralinear relation between ACh concentra-

Fig. 1 ACh-activated whole-cell currents in oocytes injected with the α -, β -, γ - and δ -subunit-specific mRNAs for *Torpedo* AChR (a, c, e) or calf AChR (b, d, f). a, b, Whole-cell current activated by 0.1 μ M ACh, bath-applied at the time indicated by the arrow. Inward current is downwards. Membrane potential, -70 mV. The current amplitude is 30 nA (a) or 960 nA (b). c, d, *I*-*V* relation of ACh-activated current. Bath application of 0.5 μ M (c) or 0.1 μ M (d) ACh. e, f, Relation between concentration of ACh and amplitude of whole-cell current response. Double logarithmic coordinates. Linear regression yields a slope of 1.7 (e) or 1.8 (f).

Methods. The pSP65 (ref. 23) recombinants carrying the calf AChR α -, β - or δ -subunit cDNA were constructed as follows. The *Sau96I*(-83)/*RsaI*(57) fragment from pcACR α 40 (ref. 12) and the *RsaI*(57)/*PstI*(108) fragment from pcACR α 18 (ref. 12) were ligated. The resulting 190-base-pair (bp) fragment was ligated with the 3.0-kilobase-pair (kb) *PstI*/*HincII* fragment from pSP65. The ligated DNA fragments were treated with *Escherichia coli* DNA polymerase I (Klenow fragment) in the presence of dGTP and dCTP and ligated. A plasmid (pc α SP1) carrying the nucleotide residues -83 to 107 of the calf AChR α -subunit cDNA was identified by colony hybridization with the above *Sau96I*/*RsaI* fragment and by restriction endonuclease analysis. The *PstI*(108)/*PstI*(428) fragment from pcACR α 18 was inserted into the *PstI* site of pc α SP1 in the same orientation as the SP6 promoter. The 366-bp *EcoRI*/*BglII* fragment from the resulting plasmid, the *BglII*(252)/*XbaI*(1,755) fragment from pcACR α 18 and the 3.0-kb *XbaI*/*EcoRI* fragment from pSP65 were ligated to yield pc α SP2. The 1.9-kb fragment from pcACR α 18 extending from the *XbaI*(1,755) site to the *PvuII* site on the vector DNA, and the 3.0-kb *SmaI*/*XbaI* fragment from pSP64 were ligated. The 1.9-kb *XbaI*/*SacI* fragment from the resulting plasmid, the 1.9-kb *EcoRI*/*XbaI* fragment from pc α SP2 and the 3.0-kb *SacI*/*EcoRI* fragment from pSP65 were ligated to yield pSP α . The 308-bp *AvaII* fragment from pcACR β 325¹³ was treated with Klenow fragment in the presence of dGTP, dCTP and dTTP and cleaved with *AccI*. The resulting 268-bp fragment was ligated with the *AccI*(162)/*BamHI*(598) fragment from pcCR β 110¹³ and the 3.0-kb *BamHI*/*SmaI* fragment from pSP65 to yield pc β SP1. The *BamHI*(598)/*BanI*(1,781) fragment and the 704-bp fragment extending from the *BanI*(1,781) site to the *PvuII* site on the vector DNA, derived from clone pcACR β 110, were ligated with the 3.0-kb *HincII*/*BamHI* fragment from pSP65 to yield pc β SP2. The 719-bp *EcoRI*/*BamHI* fragment from pc β SP1 and the 4.9-kb *BamHI*/*EcoRI* fragment from pc β SP2 were ligated to yield pSP β . The ~290-bp *PstI* fragment from pcACR δ 315¹⁵ was inserted into the *PstI* site of pSP65 in the reverse orientation as the SP6 promoter. This plasmid was cleaved with *HindIII*, treated with *Bal31* exonuclease and cleaved with *PstI*. The resulting ~260-bp fragments were ligated with the 3.0-kb *PstI*/*SmaI* fragment from pSP65. A plasmid (pc δ SP1) carrying a *SmaI* site immediately before the initiation codon was identified by DNA sequencing³³. The ~350-bp *PstI* fragment from pcACR δ 315 was inserted into the *PstI* site of pc δ SP1 in the same orientation as the SP6 promoter to yield pc δ SP2. The ~370-bp fragment from pcACR δ 496¹⁵, extending from *XbaI*(1,485) site to the *PvuII* site on the vector DNA, was ligated with the 3.0-kb *HincII*/*XbaI* fragment from pSP65 to yield pc δ SP3. The 3.3-kb *XbaI*/*EcoRI* fragment from pc δ SP3, the 431-bp *EcoRI*/*AccI* fragment from pc δ SP2 and the *AccI*(351)/*XbaI*(1,485) fragment from pcACR δ 496 were ligated to yield pSP δ . The calf AChR α -, β - and δ -subunit-specific mRNAs were synthesized *in vitro*^{22,23} using pSP α , pSP β and pSP δ (each cleaved with *HindIII*), respectively, and were capped²². The calf AChR γ -subunit-specific mRNA and the *T. californica* AChR α -, β -, γ - and δ -subunit-specific mRNAs were synthesized as described previously^{19,21}. Microinjection and incubation of oocytes were carried out as described for Table 1. All electrophysiological measurements were performed at 19–21 °C in frog Ringer's solution of the following composition (in mM) unless otherwise specified: NaCl, 115; KCl, 2.5; CaCl₂, 1.8; HEPES (pH 7.2), 10. Atropine (0.5 μ M) was added to all bath solutions to block muscarinic AChRs. Follicular cells were removed from oocytes by treatment with 1 mg ml⁻¹ collagenase (Sigma type I) in modified Barth's medium³⁴ at room temperature for 1 h. Oocytes were then held in an experimental chamber of 0.5 ml volume through which Ringer's solution was perfused continuously at 5 ml s⁻¹. Oocytes were voltage-clamped with a conventional two-micropipette voltage clamp. The voltage-recording pipette was filled with 3 M KCl, and the current injection pipette with a solution containing 0.25 M CsF, 0.25 M CsCl and 50 mM EGTA. ACh-containing solution was perfused for 10 s through the chamber. *I*-*V* relations were measured by changing the membrane potential in a rampwise fashion (40 mV s⁻¹) from -120 mV to +50 mV in the absence and presence of low (<1 μ M) ACh concentrations. The difference current was obtained by subtracting the two current records at 4-mV intervals. The reversal potential was obtained by linear interpolation between inward and outward current values measured close (<12 mV) to the reversal potential. All *I*-*V* relations were determined in extracellular solution where 1.0 mM or 1.8 mM Mg²⁺ replaced Ca²⁺ (ref. 21). The relation between ACh concentration and current amplitude was measured at -70 mV in normal Ringer's solution. ACh (2 nM–2 μ M) was bath-applied for 10 s.

tion and membrane current observed for AChR-implanted oocytes.

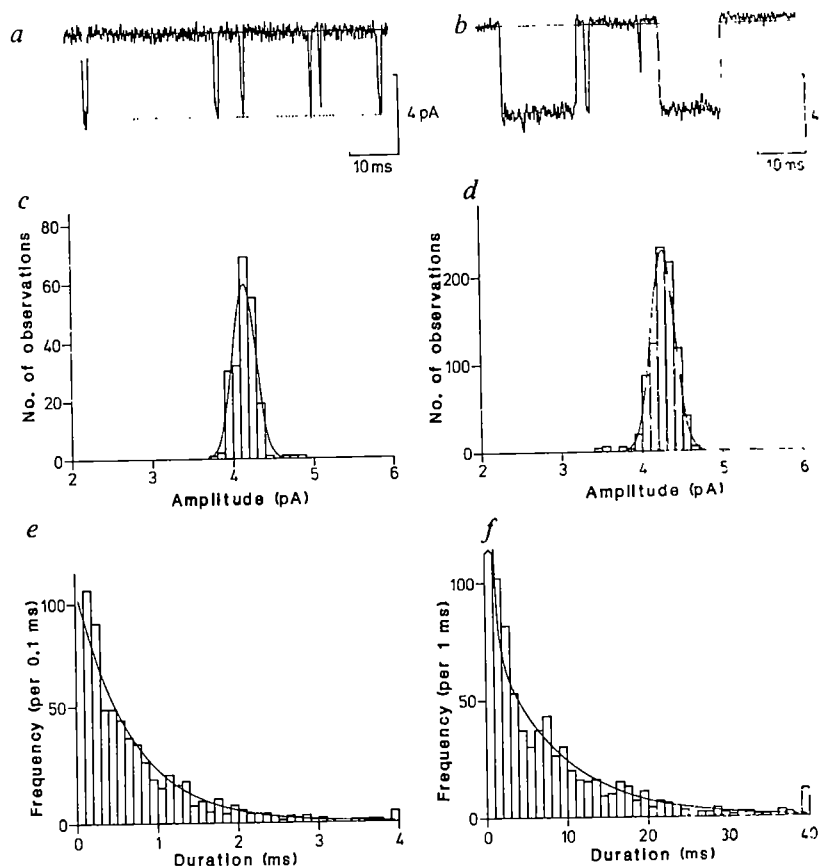

Elementary currents. Figure 2a,b compares ACh-activated single-channel currents recorded from outside-out patches isolated from oocytes injected with either the four *Torpedo* or the four calf subunit-specific mRNAs. In the two patches, the amplitudes of single-channel currents at -100 mV membrane potential were of similar size, that is, 4.1 pA and 4.2 pA for the *Torpedo* and calf AChR channels, respectively (Fig. 2c,d). The single-channel *i*-*V* relations were linear, both channels exhibiting a slope conductance close to 40 pS (Table 1).

To characterize the ion selectivity of the two classes of AChR channels, we determined the conductance sequence for

monovalent metal cations. In nominally Ca²⁺-free extracellular solution (10 mM EGTA added), the conductance sequence of the *Torpedo* and calf AChR channels was K⁺ > Cs⁺ > Na⁺ > Li⁺. The single-channel slope conductances for these cations, determined at an extracellular cation concentration of 100 mM and a driving potential of -100 mV, were (mean of two patches): 107 pS, 90 pS, 60 pS and 30 pS for the *Torpedo* AChR and 70 pS, 60 pS, 50 pS and 21 pS for the calf AChR. These values are close to the limiting conductances because the conductance did not increase further when the extracellular cation concentration was raised to 200 mM or 300 mM. The half-saturation concentrations were in the range 20–30 mM. The conductance sequence corresponds to the Eisenman sequence III or IV (ref. 27), which

Fig. 2 Properties of ACh-activated single-channel currents recorded from outside-out patches isolated from oocytes implanted with *Torpedo* AChR (*a, c, e*) or calf AChR (*b, d, f*). *a, b*, Records of single-channel currents. Inward current is downwards. Membrane potential, -100 mV. Low-pass filtering at 3 kHz (*a*) or 2 kHz (*b*) (-3 dB). At these filter settings the short interruptions of elementary currents occurring in the time range of tens of microseconds^{31,32} are largely attenuated in the records shown. *c, d*, Distribution of current amplitudes. Membrane potential, -100 mV; mean amplitude, 4.1 ± 0.14 pA (*c*) or 4.2 ± 0.15 pA (*d*) (mean \pm s.d.). *e, f*, Distribution of current durations. Membrane potential, -100 mV. The distribution in *e* is fitted by a single exponential; decay time constant, 0.61 ms. The distribution in *f* is fitted by the sum of two exponentials; decay time constants, 0.4 and 8.6 ms. Only the slower component is shown fully in *f*. The last bin includes durations longer than 4 ms (*e*) or 40 ms (*f*). The first bin in *f* has a roof to indicate that it extends beyond the scale.

Methods. Single-channel currents were measured in outside-out and cell-attached membrane patches³⁵. All experiments were done at 19 – 21 °C on oocytes bathed in normal frog Ringer's solution. The vitelline membrane covering the oocyte was removed mechanically to allow close contact between pipette and oocyte plasma membrane with a seal resistance >10 G Ω . Mechanical removal of the vitelline membrane was facilitated by placing the oocyte for 5 min in hypertonic 'stripping solution' (in mM: K-aspartate 200; KCl 20; MgCl₂ 1; EGTA 10; HEPES (pH 7.2) 10). The pipette solution in the outside-out patch recording configuration had the following composition (in mM): KCl 20; KF 80; MgCl₂ 1; EGTA 10; HEPES (pH 7.2) 10. Following formation of an outside-out patch, ACh was applied from another pipette the opening of which (≈ 500 μ m diameter) was located close to the membrane patch (~ 100 μ m distance). The ACh concentration in this pipette was 0.1 – 5 μ M. The conductance sequences for different alkali metal cations were measured in cell-attached patches. Thick-walled patch pipettes of small (≈ 0.5 μ m diameter) tip openings were used. With these pipettes the occurrence of endogenous stretch-activated single-channel currents is significantly reduced (C.M. *et al.*, in preparation). K⁺, Cs⁺, Na⁺ or Li⁺ were present at 100 mM in the pipette solution which contained also 10 mM EGTA and 10 mM HEPES (pH 7.2). Conductance values represent the slope conductance measured at a driving potential of -100 mV. Patch-clamp currents were measured with a LIST EPC-7 amplifier and recorded on magnetic tape (Racal Store 4). After appropriate filtering, current records were digitized at 20–100 μ s per point and analysed on a PDP 11/73 computer. For analysis of the amplitude and duration of single-channel current records of the *Torpedo* AChR, the method of time course fitting³⁶ was used. Currents mediated by the calf and hybrid AChRs were analysed also by the threshold-crossing method³⁶; the threshold was half the full amplitude. Amplitude distributions contained only fully resolved current pulses and were fitted by single Gaussians. Single channel current *i*–*V* relations in outside-out patches were measured in the voltage range -120 to -20 mV. Distributions of durations were fitted with either one or two exponential components using the maximum likelihood method³⁶. The Patternsearch or the Simplex method was used to obtain the parameters of the distribution³⁶. The average duration of elementary currents in the text and in Table 1 refers to the decay time constant of the slower component.

suggests, in terms of Eisenman's selectivity theory, a relatively weak interaction between the ion in the channel and an anionic binding site on the channel wall in both *Torpedo* and calf AChR.

Whereas the ion selectivity and transport properties of the *Torpedo* and calf AChR channels were comparable, their gating behaviour differed markedly. The average duration of elementary currents flowing through calf AChR channels was much longer than that observed for the *Torpedo* AChR channel. Figure 2*e, f* shows histograms of current durations at -100 mV membrane potential. Distributions of current durations were fitted satisfactorily only by the sum of two exponential components, except for some measurements of the *Torpedo* AChR channel, where the number of resolved short durations was too small to allow a reliable estimate of the decay time constant of the faster component. The slower component predominated in all experiments and we therefore restricted the analysis to this component. The average duration of single-channel currents was 0.6 ms for *Torpedo* AChR at membrane potentials of -110 mV to -70 mV, in striking contrast to the 7.6 ms obtained for calf AChR (Table 1).

Another difference between the two AChR channels was revealed when the average duration of elementary currents was measured at different membrane potentials. The average current duration of the *Torpedo* AChR channel was not significantly

voltage-dependent; in one experiment, measured at membrane potentials of -50 mV and $+50$ mV in the same membrane patch, they were 0.48 and 0.46 ms, respectively. Elementary currents of the calf AChR channel (Fig. 2*f*) had average durations of 8.6 ms, 6.8 ms and 3.9 ms at membrane potentials of -100 mV, -50 mV and $+50$ mV, respectively, suggesting that the gating reaction of the calf AChR is voltage-dependent. This probably underlies the inward rectification in the whole-cell *I*–*V* relation for the calf AChR (see Fig. 1*d*).

Hybrid AChR channels

To determine which subunit is responsible for the marked difference in gating behaviour between the *Torpedo* and calf AChRs, we constructed hybrid AChRs by injecting oocytes with the corresponding combinations of *Torpedo* and calf subunit-specific mRNAs, then analysed the functional properties of the hybrid AChRs.

α -Hybrid AChR. The hybrid AChR formed in oocytes injected with the calf α -subunit-specific mRNA and the *Torpedo* β -, γ - and δ -subunit-specific mRNAs (α -hybrid AChR) showed an average channel activity somewhat higher than that of the *Torpedo* AChR but much lower than that of the calf AChR (Fig. 3*a*, Table 1). The whole-cell *I*–*V* relation was almost linear, and the reversal potential close to 0 mV (Fig. 3*b*, Table 1); the dose-

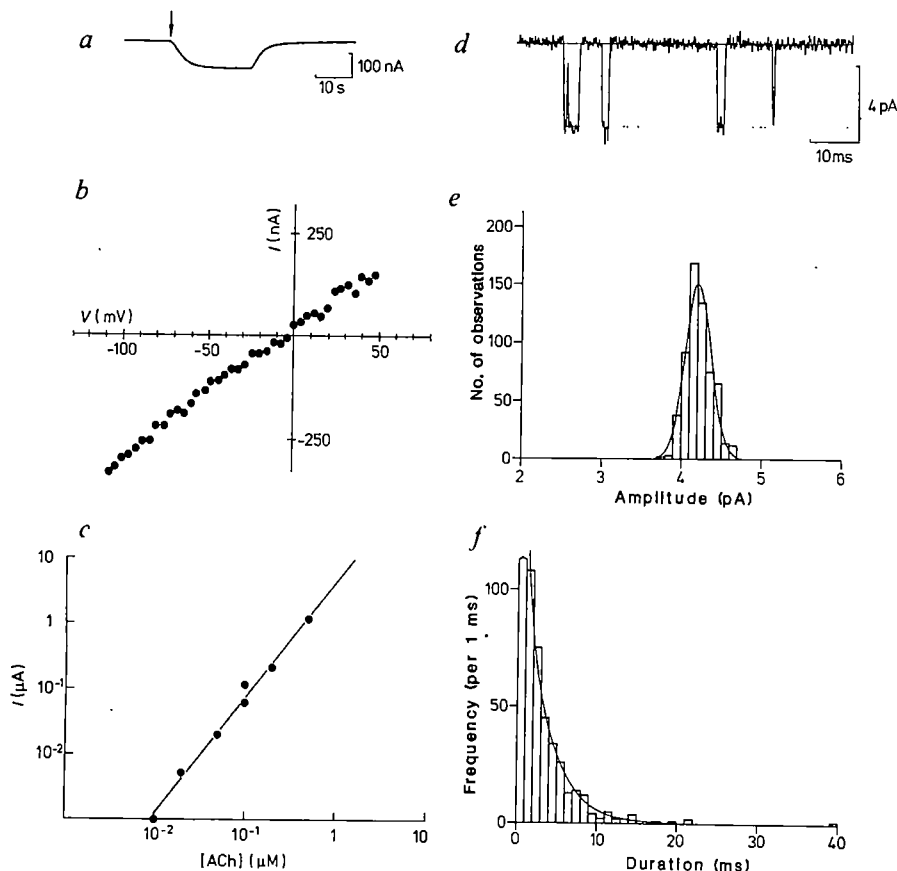

Fig. 3 Whole-cell (*a-c*) and single-channel (*d-f*) current measurements for oocytes implanted with the α -hybrid AChR. *a*, Whole-cell current activated by $0.1 \mu\text{M}$ ACh bath-applied at the time indicated by the arrow. Inward current is downwards. Membrane potential, -70 mV . The current amplitude is 120 nA . Note that the scales are the same as in Fig. 1*a*. *b*, *I-V* relation of ACh-activated current between -120 mV and $+50 \text{ mV}$ membrane potential. *c*, Relation between ACh concentration and whole-cell current response. Double logarithmic coordinates. The slope of the straight line fit is 1.8 . *d*, Single-channel currents. Inward current is downwards. Membrane potential, -100 mV . Low-pass filtering at 2 kHz (-3 dB). *e*, Distribution of current amplitudes. Membrane potential, -100 mV . The mean amplitude is $4.2 \pm 0.16 \text{ pA}$. *f*, Distribution of current durations. Membrane potential, -100 mV . Line represents fit by the sum of two components; decay time constants, 0.41 ms and 3.2 ms . Only the slower component is shown fully. The last bin includes durations $>40 \text{ ms}$.

response curve yielded a Hill coefficient of 1.8 (Fig. 3*c*). The properties of whole-cell currents (Table 1) indicate that the α -hybrid AChR behaves much like the *Torpedo* AChR.

Figure 3*d* shows single-channel current recordings of the α -hybrid AChR, and Fig. 3*e, f* the distribution of current amplitudes and of current durations at -100 mV membrane potential. The channel conductance of this hybrid AChR (42 pS) was virtually the same as that of the parental AChRs (Table 1). The mean duration of single-channel currents of this hybrid (2.5 ms) was longer than that of the *Torpedo* AChR (Table 1). The average duration of single-channel currents of the α -hybrid AChR was essentially independent of membrane potential; the values obtained at membrane potentials of -100 mV and $+50 \text{ mV}$ were 3.2 and 2.7 ms , respectively (Fig. 3*f*).

δ -Hybrid AChR. The hybrid AChR formed in oocytes injected with the calf δ -subunit-specific mRNA and the *Torpedo* α -, β - and γ -subunit-specific mRNAs (δ -hybrid AChR) showed an average channel activity ~ 60 -fold higher than that of the *Torpedo* AChR and comparable to that of the calf AChR (Fig. 4*a*, Table 1). The whole-cell *I-V* relation was curved, indicating that the ACh-activated conductance mediated by the δ -hybrid AChR channel rectifies and the reversal potential was close to 0 mV (Fig. 4*b*, Table 1). The dose-response curve gave a Hill coefficient of 1.7 (Fig. 4*c*, Table 1).

Single-channel current records (Fig. 4*d*) revealed that the channel conductance and gating behaviour of the δ -hybrid AChR are similar to those of the calf AChR. Figure 4*e* and *f* show the distribution of current amplitudes and of current durations at -110 mV membrane potential, respectively. The channel conductance of the δ -hybrid AChR (35 pS) was nearly the same as that of the parental AChRs (Table 1). However, the average duration of elementary currents was 8.6 ms , more than 10 -fold longer than that of the *Torpedo* AChR and comparable to that of the calf AChR (Table 1). The average current duration of the δ -hybrid AChR channel was voltage-dependent being 10.3 ms and 3.5 ms at membrane potentials of -110 mV and $+50 \text{ mV}$, respectively (Fig. 4*f*).

β - And γ -hybrid AChRs. Two additional hybrid AChRs were produced by injecting oocytes either with the calf β -subunit-specific mRNA and the *Torpedo* α -, γ - and δ -subunit-specific mRNAs (β -hybrid AChR) or with the calf γ -subunit-specific mRNA and the *Torpedo* α -, β - and δ -subunit-specific mRNAs (γ -hybrid AChR). Oocytes containing these hybrid AChRs showed a very low channel activity (Table 1). This is probably due to an extremely low density of the β - and γ -hybrid AChRs expressed in the oocyte membrane because the α -BTX binding activity on the cell surface was markedly diminished despite the considerable activity found in the cell extract (Table 1). It thus appears that in these hybrids subunit assembly is impaired, forming aberrant complexes. Therefore, we did not investigate channel properties of the β - and γ -hybrid AChRs.

Conclusions

Both *Torpedo* and calf AChR channels, produced in the *Xenopus* oocyte membrane by translation of the α -, β -, γ - and δ -subunit-specific mRNAs, exhibit virtually the same conductance. In Ringer's solution, with Na^+ as the main charge carrier, the conductance is $\sim 40 \text{ pS}$. Any subunit of the *Torpedo* AChR can be replaced by the corresponding subunit of the calf AChR to form functional channels. The conductances of α - and δ -hybrid AChR channels are similar to those of the parental AChR channels. These observations are consistent with the high degree of amino-acid sequence homology between corresponding subunits of the *Torpedo* and calf AChRs⁶⁻¹⁵. Each subunit contains five putative transmembrane segments^{6-9,11-15,21,28,29} which are involved directly in the formation of the channel²¹.

In contrast to the uniform conductance of the *Torpedo*, calf and hybrid AChR channels, their gating behaviour differs widely. The average duration of elementary currents of the calf AChR channel is more than 10 -fold that of the *Torpedo* AChR channel. The mean current duration of the α -hybrid AChR channel lies between those of the *Torpedo* and calf AChR channels, while that of currents through the δ -hybrid AChR channel is comparable to that of the calf AChR channel. There-

fore, it seems plausible that presently unidentified functional domains of the calf δ - and α -subunits determine the longer duration of elementary currents.

The average duration of elementary currents through AChR channels is determined, in the framework of the simple two-step reaction mechanism (1) described above, by at least three reaction steps: channel opening, channel closing and dissociation of the agonist. The increased duration of elementary currents in the δ -hybrid and α -hybrid AChR channels, as compared with that of the *Torpedo* AChR channel, could reflect a difference in any of the rate constants governing these steps. The voltage dependence of whole-cell $I-V$ relations and single-channel current durations might give a clue as to which reaction step is different. In frog endplate, the curvature of the whole-cell $I-V$ relation and the voltage sensitivity of the average single-channel current duration are determined by the voltage dependence of

channel closing^{30,31}. The observation that both the calf AChR and the δ -hybrid AChR behave like the frog AChR would then be consistent with the hypothesis that the δ -subunit determines the channel-closing step. The α -hybrid AChR is also characterized by an average current duration somewhat longer than that of the *Torpedo* AChR but which is voltage-insensitive, suggesting that the α -subunit may mainly determine another reaction step, such as channel opening or agonist dissociation.

We thank Dr Jon Lindstrom for the monoclonal antibody mAb210, Dr Motoy Kuno for helpful discussions, and Drs S. DeRiemer and R. Eckert for reading the manuscript. This investigation was supported in part by research grants from the Ministry of Education, Science and Culture of Japan, the Mitsubishi Foundation and the Japanese Foundation of Metabolism and Diseases.

Shepherding model for Neptune's arc ring

Jack J. Lissauer*

Department of Astronomy, University of California, Berkeley, California 94720, USA

An incomplete arc ring has recently been discovered around Neptune¹. Here, a model to explain the confinement of this ring is developed. The ring may be azimuthally confined near a triangular (Trojan) point of an undiscovered satellite of Neptune. Radial diffusion of the ring particles can be prevented by shepherding torques of another moon. Two satellites with diameters of 100–200 km would be sufficient to confine the ring; such moons would be too small to have been photographed from Earth.

The arc ring of Neptune¹ differs substantially from other known planetary rings. Whereas the rings of Jupiter, Saturn and Uranus completely encircle these planets, Neptune's ring appears to be an incomplete arc, spanning only a small fraction of an ellipse. The exact dimensions of the ring are poorly constrained, as it has only been observed by stellar occultation. Detections of the ring at three separate telescopes imply that it is located at a distance of $r \sim 67,000$ km from Neptune's centre, has a width $w \sim 15$ km, an optical depth $\tau \sim 0.08$, and a length of at least 100 km, all assuming that the ring lies in Neptune's equatorial plane¹. Approximately 10 other stellar occultations of the Neptune system have failed to show such a ring, although an event observed at a similar distance from Neptune by two closely spaced telescopes during one occultation, which has been tentatively attributed to a satellite (provisionally named 1981N1)², could possibly be an optically very thick ring. The current detection rate leads to a crude estimate that the arc ring spans $\sim 10\%$ of the circumference around Neptune.

Theories developed to explain the rings of other planets do not fully explain arc rings. If the particles in an arc ring were unconstrained, they would spread out azimuthally because of the shorter orbital periods of particles nearer the planet. An arc ring 15-km wide located 67,000 km from Neptune's centre would spread out to encircle the entire planet in less than 3 yr. Interparticle collisions and, for small particles, Poynting–Robertson drag, would cause radial spreading on a timescale of less than 10^8 yr (ref. 3), which is short compared with the age of the Solar System. Thus, some active confining mechanism is required, unless the arc ring is extremely young.

Torques caused by observed moons are responsible for several sharp boundaries in Saturn's rings^{4–8}. Undetected moonlets are believed to be responsible for confining the uranian rings³, as well as several features in Saturn's rings⁹. Although no discontinuous arc ring is seen (except possibly within the Encke gap in Saturn's A ring⁹), several of the resonantly produced features are eccentric^{4,7,8}. Satellites are thus capable of producing azimuthally variable ring structure.

Jupiter confines the Trojan asteroids to a limited azimuthal range around the stationary triangular (Lagrange) points of the Jupiter–Sun system, L_4 and L_5 . These asteroids are in a 1:1 orbital commensurability with Jupiter, orbiting 60° ahead of and behind the planet. Similar Lagrange point librators share orbits with some of Saturn's many moons^{4,10,11}. One early model of the uranian rings proposed that they were confined in a similar, although less tightly bound, horseshoe resonance lock¹². However, although individual satellites and groups of non-interacting satellites orbit stably in such resonance locks, collisional rings cannot be confined in such a manner. The problem arises because the triangular points are potential maxima (which are only stable because of Coriolis forces¹³), and interparticle

Fig. 1 Neptune's arc ring viewed from above Neptune's pole, as predicted from the present model. The ring appears stationary in the frame rotating with the Lagrange point moon, although the individual ring particles librate slowly about the triangular point in the direct indicated. The frame rotates in the anticlockwise direction with respect to inertial space.

collisions, which dissipate energy, drive particles away from energy maxima. Although a satellite can azimuthally confine ring particles which have semimajor axes (nearly) the same as its own, interparticle collisions and other dissipative effects will cause radial spreading similar to that of an unconfined ringlet.

Saturn's F ring is confined to a radially narrow strand caused by torques from 'shepherding' moons on both sides⁴. Undetected shepherding moons are believed to confine the nine narrow rings of Uranus³. Shepherding is possible because a moon exerts a torque which repels nearby ring material. This torque falls off rapidly with distance from the moon. Ring particles initially orbiting between two moons are thus confined to a ring whose radial width is determined by a balance between diffusive spreading and satellite torques³.

We suggest that the arc ring of Neptune is azimuthally confined near a triangular Lagrange point of an undetected satellite (or, possibly, 1981N1), and radially confined by at least one shepherding moon on a nearby orbit (Fig. 1). One shepherding moon is sufficient because the ring particles' orbits are alternately interior to, and exterior from, that of the confining Lagrange point satellite. The shepherding moon, which may orbit either interior to, or exterior from, the ring, repels all the ring particles. However, when a particle is on the half of its libration cycle which brings it nearer the shepherd, the magnitude of the repulsive torque, which at the time is pushing the ring particle towards the orbit of the Lagrange point moon, is greater than the magnitude of the repulsive torque pushing the particle away from the Lagrange point moon during the other half of its libration cycle. Thus, the shepherd's net effect is to stabilize the 1:1 resonance between the ring particles and the Lagrange point moon. In celestial mechanics terminology, the torque caused by the shepherding satellite acts, on average, to decrease the Jacobi constants of the ring particles, driving them closer to L_4 or L_5 . Note that energy conservation is not violated; the energy lost in inelastic collisions between ring particles is resupplied to the ring from orbital energy of the rings and moons. The shepherding moon is repelled from the ring in the process, but the timescale for this to occur may be longer than the age of the Solar System. (Alternatively, tidal torques on the moons by Neptune may counteract this repulsion.)

The combination of a Lagrange point moon and a shepherding moon on a nearby orbit is thus qualitatively capable of producing the arc ring structure observed around Neptune. Quantitative estimates will now be made which show that Neptune's ring may be confined by moons of sufficiently small size that they would not have been photographically detected from Earth.

* Present address: Department of Physics, University of California, Santa Barbara, California 93106, USA.

To zero order, the orbits of the ring particles are keplerian ellipses about Neptune. The semimajor axes of these ellipses are perturbed by the lagrangian moon, causing the ring particles to librate about one of the moon's triangular points with periods of the order of 1 yr. Perturbations by the shepherding moon induce eccentricities in the ring particles. The damping of these eccentricities results in a radial drift on a much longer timescale, comparable with the timescale for diffusive spreading of the ring.

The relationship between the radial, δr , and angular, θ , separations of a given ring particle from the Lagrange point satellite is:

$$\frac{3}{4} \left(\frac{\delta r}{r} \right)^2 + \frac{m}{M} \left(\frac{1}{\sin(\theta/2)} - 2 \cos \theta + 2 \right) = C - 3 \quad (1)$$

where r is the satellite's semimajor axis, m is the mass of the Lagrange point moon, M is Neptune's mass, and C is the Jacobi constant¹⁴. The Jacobi constant depends on the amplitude of the particle's libration about the triangular point, and differs for different ring particles. For a given ring particle, the Jacobi 'constant' varies slowly, in response to torques from the shepherding moon and interparticle collisions. The width of a particle's libration at a given angle can be computed from equation (1) to be:

$$w = 2\delta r = \frac{4r}{\sqrt{3}} \left\{ C - 3 - \frac{m}{M} \left(\frac{1}{\sin(\theta/2)} - 2 \cos \theta + 2 \right) \right\}^{1/2} \quad (2)$$

and the length of the arc, l , is:

$$l = r(\theta_2 - \theta_1) \quad (3)$$

where the θ_i are the angles at which $\delta r = 0$ (see equation (1)). Presumably, the shepherding moon confines the ring particles to a maximum value of C (and thus of δr). If the arc ring subtends no more than 10% of the circumference of the satellites orbit, and its maximum width is at least 15 km, then a lower bound on the lagrangian satellite's mass is 4.5×10^{21} g; this bound may be reduced to 0.48×10^{21} g if an arc of 156° (the maximum possible libration amplitude for tadpole orbits) is allowed. Assuming a density of 1 g cm^{-3} , a moon of mass 4.5×10^{21} g would have a diameter ~ 200 km. The tentatively detected moon 1981N1, which presumably has a diameter between 100 and 1,000 km (ref. 2), is thus a candidate for the Lagrange point satellite.

The size(s) of the shepherding satellite(s) are less well constrained. The torque per unit ring mass, T_s , on a ring at radius r caused by a shepherding satellite of mass m_s at radius r_s is^{3,15}:

$$T_s = 0.4 \text{ sign}(r - r_s) \left\{ \frac{Gm_s}{\Omega(r - r_s)^2} \right\}^2 \quad (4)$$

where Ω is the angular frequency of the ring particles. The differential shepherding torque across the ring must balance the viscous and other diffusive torques within the ring (including the extra diffusive torque caused by stirring by the shepherding moon¹⁶). Assuming just one shepherding moon, its mass would be roughly:

$$m_s \sim 3 \times 10^{21} \left(\frac{\nu}{10} \right)^{1/2} \left(\frac{r - r_s}{10^8} \right)^{5/2} \quad (5)$$

where ν is the effective kinematic viscosity of the ring and all quantities are in c.g.s. units. Estimates of ν for Saturn's rings range between 5 and $260 \text{ cm}^2 \text{ s}^{-1}$ (refs 8, 17). Thus, the shepherding moon would be ~ 120 km in diameter if its orbit was 1,000 km from that of the ring; the required diameter would scale slightly slower than linearly with its distance from the ring. An arc ring which has a maximum width $\gg 15$ km would permit a smaller shepherd for a given separation and viscosity; however, it would require a significantly larger Lagrange point satellite. If there were shepherds on both sides of the ring, required masses would decrease by a factor of $\sqrt{2}$.

Thus, Neptune's arc ring may be confined by two nearby moons each ~ 100 – 200 km in diameter. One of the moons would

restrain the ring azimuthally near one of its stable triangular points with Neptune. The other moon, circulating on a different orbit, would confine the ring radially in the standard shepherding manner. Other configurations are also possible. For example, the shepherding moon may be coorbital with the Lagrange point moon, but have a larger libration amplitude than that of the ring. The problem with this latter scenario is that the torque from the ring would drive the shepherd away from the coorbital resonance; either the moons would have to be much more massive than the ring (so the timescale would be very long) or the system would have to be supplied with energy from an external source (such as tidal torque from the planet).

Further observations of Neptune's arc ring by stellar occultations, the Hubble Space Telescope and, in 1989, by the Voyager 2 spacecraft, should greatly increase our knowledge of this newly discovered structure, and determine whether the model presented here is accurate. A search for arc rings orbiting the other giant planets may also prove fruitful.

Timescale-invariant profile of the type II bursts from the Rapid Burster

Y. Tawara*, N. Kawai†, Y. Tanaka†,

The Rapid Burster is a unique X-ray source which produces rapidly repetitive X-ray bursts. Each rapid burst shows a characteristic structure in its decay part comprising successive peaks. We have now discovered that the structure of each individual burst shows a nearly identical profile except for the timescale, which differs largely from burst to burst; the profile of the decay is timescale invariant. This invariance holds over a wide range of timescales to at least a factor of 30. Furthermore, we have found that the heights of successive peaks as well as the intervals between them decrease with time according to a common arithmetic rule.

The rapidly repetitive bursts from the Rapid Burster are probably due to chopped accretion flow caused by some instabilities¹. Hoffman *et al.*² designated these bursts type II bursts and those interpreted as thermonuclear flashes as type I bursts. Here, we shall discuss the remarkable characteristics of the structure in the decay part of type II bursts from the Rapid Burster.

We observed the rapid burst activities of this source from Tenma in August 1983 (ref. 3) and July 1984. Each burst exhibits

Fig. 1 *a*, A portion of the rapid burst activity (1983). *b*, Detail of the profiles of three bursts with different length. Timescale in these diagrams is in units of the characteristic time τ which is determined from a cross-correlation analysis performed between the two dashed lines for each burst.

a significant structure in the decay part. Long flat-topped bursts with durations exceeding 40 s show one or two humps in the decay. Bursts of shorter duration commonly comprise more than two peaks (Fig. 1). Clearly, the timescale of the structure depends on the burst duration; the longer the burst duration, the slower is the excursion of the decay structure.

There is a striking similarity in the form of the decay structure between bursts, except that the timescale of the structure differs from burst to burst. In order to examine the similarity in more detail, we performed a cross-correlation analysis of the decay profile between bursts by varying timescales, and determined the relative timescale for each burst. Cross-correlation was taken between the dashed lines shown in Fig. 1. For convenience, we define the characteristic time τ for each burst as being the interval between the first and second peaks in the decay, as also indicated in Fig. 1.

We then constructed composite profiles from many bursts by normalizing the characteristic times, as shown in Fig. 2 for different ranges of τ . The number of bursts superimposed is indicated on each figure.

In Figs 1 and 2 we see that the decay structure is essentially independent of the timescale. In other words, the profile of the decay is timescale invariant and can be expressed by a single function $F(t/\tau)$ with time t . Obviously, the profile is not of a simple damping oscillation but more complex. For instance, the second and the third peaks are close together and form a broad hump. Such fine detail is not eliminated by superimposing many bursts. This fact implies that, independently of the length of timescale of each burst, the structure is intrinsic and solid, as in the case of the X-ray pulsar profiles. Furthermore, we stress that the timescale invariance of the decay profile holds for a wide range of the characteristic time τ from 9 to 0.3 s, the shortest limit with our time resolution.

As regards the detail of the decay structure, we note that there is a specific trend in the heights and intervals between successive peaks. First, the peak height appears to decrease linearly with time. Second, the interval is uneven and gradually shortened towards the end of decay. The observed pattern indeed suggests the presence of a certain regularity.

We discovered an interesting rule that satisfactorily determines the relative positions of the successive peaks. Suppose we assign the positions of the broad main peak (0th peak) and the following peaks, respectively, as indicated in Fig. 3. We find

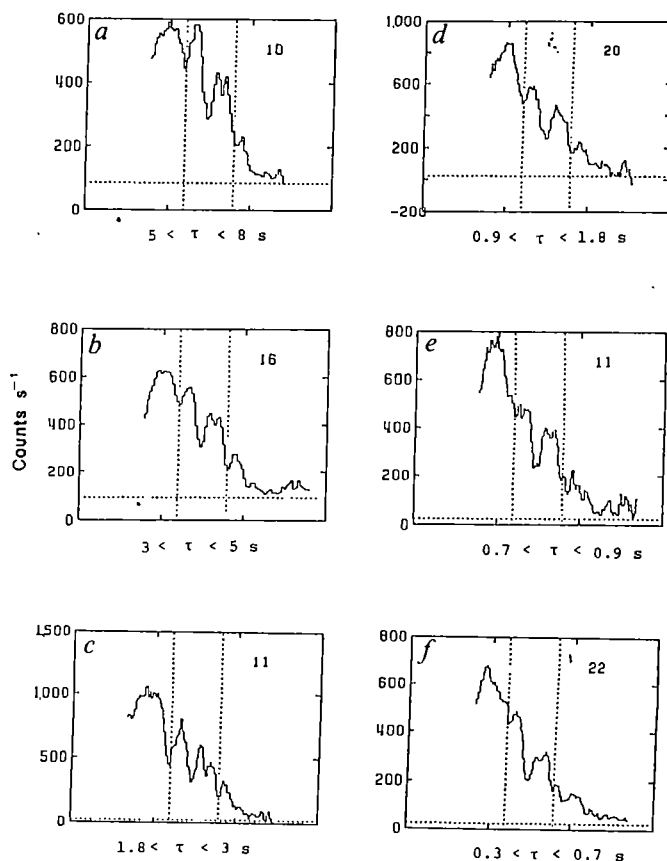

Fig. 2 Composite profiles of type II bursts constructed by normalizing the characteristic times, for six different ranges of τ . The number of bursts superimposed is indicated in each panel. *a-c* are from 1983 August data taken with a time resolution of 0.5 s, and *d-f* are from 1984 July data with a time resolution of 0.125 s.

that $(X_4 - X_2)/(X_2 - X_0) = (X_5 - X_3)/(X_3 - X_1) = \alpha$, with α approximately 0.57, where X_n is the time of the n th peak in units of the characteristic time. In other words, the successive peak positions are 'phased' in such a way that the intervals between the even-numbered peaks and those between the odd-

Fig. 3 Composite profile of the type II bursts of 1983 ($2.5 < \tau < 3.5$ s) (a) and 1984 ($2.0 < \tau < 3.5$ s) (b) activities. Vertical bars indicate the positions and heights of the peaks determined as described in the text.

numbered peaks respectively compose a geometric series with the same multiple α , although the peaks after the fourth are not always statistically significant. From the relative phase of the odd-numbered peaks with respect to the even-numbered ones, we define $(X_3 - X_1)/(X_2 - X_0) = \beta$, then $(X_1 - X_0)/(X_2 - X_0) = (1 - \beta)/(1 - \alpha)$, so that the geometric series of the even-numbered and odd-numbered peaks converge at the same point.

The same rule seems to hold for the heights of successive peaks. Namely, the successive peak heights, Y_n for the n th peak, roughly satisfy the following relations: $Y_2/Y_0 = Y_4/Y_2 = Y_6/Y_4 = \alpha$ for the even-numbered and the odd-numbered peaks, with the same value of α as determined for the respective intervals; besides, $Y_1/Y_0 = \beta$. Thus, the common rule that applies to the intervals and heights makes the successive peaks appear to decrease linearly with time.

The above rule holds equally for the rapid bursts observed in 1983 as in 1984. There is a significant difference in the peak luminosity as well as the time-averaged luminosity between the activities of these two years. The bursts in the 1984 activity are on average roughly twice as luminous as those of 1983. The time-averaged luminosity during the 1984 activity is also about double that of 1983. It is important that, despite this difference, the values of α are the same in the two separate activities. However, a subtle difference exists in the relative phase of the odd-numbered peaks with respect to the even-numbered peaks. In the 1983 bursts, the odd-numbered peaks are shifted slightly earlier in phase than the corresponding peaks in the 1984 bursts; this is most noticeable in the smaller separation between the second and third peaks of the 1983 profile. The difference is expressed in terms of β which are 0.81 and 0.77 for the activities in 1983 and 1984, respectively.

If one assumes that the luminosity of a burst at a given time is determined by the instantaneous accretion rate, the above findings on the decay structure imply the presence of some complex flow-control mechanism. One might speculate that the structures are already prepared in the accretion disk (for example, regular concentric rings similar to the Saturn's rings). However, any model should explain the facts that the timescale-invariant profile is reproduced over a very wide range of burst duration while the peak luminosity (peak accretion rate) is independent of the burst duration and that the pattern is not influenced by the change of average accretion rate.

Search for a heavy neutrino in the β -decay of ^{35}S

V. M. Datar*, C. V. K. Baba†, S. K. Bhattacharjee†
C. R. Bhunya† & Amit Roy†

* Nuclear Physics Division, Bhabha Atomic Research Centre, Bombay 400 085, India

† Tata Institute of Fundamental Research, Homi Bhabha Road, Bombay 400 005, India

Recent experimental evidence¹ suggests that the neutrino (strictly, an antineutrino) emitted in the β -decay of tritium is a mixture of two mass eigen states $|\nu_1\rangle$ and $|\nu_2\rangle$ where $|\nu_e\rangle = \cos \theta |\nu_1\rangle + \sin \theta |\nu_2\rangle$ with $m_{\nu_1} < 50$ eV and $m_{\nu_2} = 17.1 \pm 0.2$ keV and $\sin^2 \theta = 0.03$. This conclusion is based on the observation of a 'kink' in the Fermi-Kurie plot^{2,3} of the electron energy spectrum at an energy 17.1 keV below the end point. Such an observation, if confirmed, will have far-reaching consequences in cosmology and particle physics^{4,5}. In the experiment reported here, a search was made for such an admixture in the β -decay of ^{35}S . We fail to confirm the presence of mixing of neutrinos with mass 17.1 keV and place an upper limit on such an admixture of 0.6% (90% confidence level).

The β -decay of ^{35}S has been studied extensively in magnetic spectrometers^{6,7}. ^{35}S decays with a half-life of 87.4 days to the ground state of $^{35}\text{Cl}(3/2^+ \rightarrow 3/2^+)$ with 100% branching with an end-point energy of 167.4 ± 0.2 keV (ref. 8). The transition is an allowed one, with a $\log ft = 5.0$. The linearity of the Fermi-Kurie plot has been established down to an energy of 20 keV (ref. 7). However, from the earlier data, particularly from the Fermi-Kurie plots which are usually available in the literature, it is not easy to discover any discrepancy like a 'kink' at around 150 keV, which is expected if a heavy neutrino admixture is present.

In the present experiment, a ^{35}S source in the form of BaSO_4 of less than $10 \mu\text{g cm}^{-2}$ thickness, was deposited onto a $90 \mu\text{g cm}^{-2}$ aluminized polypropylene foil. The β spectrum was measured with a shielded windowless liquid nitrogen-cooled Si(Li) detector of diameter 28 mm and thickness 3 mm fabricated in our laboratory. The detector had a resolution of 3.5 keV at 120 keV. The spectrometer was calibrated with conversion electron lines from ^{57}Co and $^{99\text{m}}\text{Tc}$ and γ -ray lines from $^{114\text{m}}\text{In}$ and ^{137}Cs . The conversion electron spectra were used to obtain the response function of the detector. The back-scattered fraction of electrons from the Si(Li) detector, in the energy range of

Fig. 1 The shape factor of the β -spectrum of ^{35}S as obtained in the present experiment (\bullet). Error bars, ± 1 s.d. Also shown (---) is the expected shape for a 3% branch in this β -decay where a 17-keV neutrino is emitted, with $\sin^2 \theta = 0.03$.

Fig. 2 Upper limit on $\sin^2 \theta$ at the 90% confidence level, obtained from the present experiment and shown as a function of the assumed neutrino mass. The region above the curve is excluded by this experiment. The single point shown at the top represents the result derived from Simpson's experiment¹.

130 keV, was determined to be 0.20 ± 0.02 at a source-detector distance of 8 cm, as used in the experiment. From a comparison of the electron and γ spectra of ^{99m}Tc , a dead layer of the order of 2 mg cm^{-2} was found to be present on the entrance window of the detector. Such a dead layer would not allow an accurate measurement of the β spectrum down to very low energies of $\sim 50 \text{ keV}$. However, this would not appreciably affect the shape of the spectra in the limited energy range 130–170 keV, hence we restricted our analysis to this energy region after correcting for the energy loss in the dead layer.

The counting rate was kept below 1,000 Hz and a time constant of $0.5 \mu\text{s}$ was used for the amplifier. Perspex collimators were used to block the electrons scattered from the chamber walls reaching the detector. These collimators also reduced the external bremsstrahlung produced from the walls of the vacuum chamber. The efficiency of the detector was determined from 75 keV to $\sim 1 \text{ MeV}$ using the internal conversion lines of the decay of ^{152}Eu . The measured efficiency was found to be constant to within $\pm 3\%$ in this energy region. By interpolation, the energy variation of efficiency can be estimated to be less than $\pm 0.2\%$ over the small energy range (130–170 keV) in which the data have been analysed. The measured β -spectrum was corrected for background and pile-up effects. The theoretical β spectrum for ^{35}S was calculated for $m_\nu = 0$ using the Fermi functions of Behrens and Janecke⁹ and was folded with detector response function. The ratio of the experimental to the calculated spectrum normalized to 1 is the shape factor, and is shown in Fig. 1. The measured end point obtained is in agreement with the accepted value. If there is an admixture of heavy neutrinos of mass m with a mixing amplitude $\sin \theta$, such a shape factor $C(W)$ would have the form

$$C(W) = \cos^2 \theta + \sin^2 \theta \left[1 - \frac{m_\nu^2}{(W_0 - W)^2} \right]^{1/2} \text{ for } W < (W_0 - m_\nu)$$

$$C(W) = \cos^2 \theta \text{ for } (W_0 - m_\nu) < W < W_0$$

where W is the electron energy and W_0 the end-point energy. Also shown in Fig. 1 (broken curve) is the expected shape factor, with assumed values of $\sin^2 \theta = 0.03$ and $m_\nu = 17 \text{ keV}$ as reported by Simpson¹. It is clear from the figure that such a curve lies well outside our experimental limits, ruling out the existence of a mixture of a heavy neutrino of mass 17 keV and $\sin^2 \theta = 0.03$, in the β -decay of ^{35}S . In Fig. 2 the upper limits for $\sin^2 \theta$, at the 90% confidence level, derived from the above shape factor are shown as a function of the mass of the neutrino. It is clear that a heavy neutrino admixture of more than 1% does not exist in ^{35}S β -decay for the neutrino mass range 5–30 keV. Our results,

together with those of Schreckenbach *et al.*,¹⁰ do not suggest the presence of a heavy neutrino admixture above 1% for the neutrino mass range of 5–460 keV.

We thank Radio Isotope Division, BARC, for providing the ^{35}S activity, D.C. Ephraim for preparing the source, and Arvind Jain and Probir Roy for useful discussions.

Solid solution in plumbous potassium oxysilicate affected by interaction of a lone pair with bond pairs

Paul B. Moore*, Pradip K. Sen Gupta† & Elmer O. Schlemper‡

During explorations of the chemical crystallography of lead silicates, the synthetic phase $\text{K}_2\text{Pb}_4\text{Si}_8\text{O}_{21}$ (here KPS), attracted our attention. Clear crystals when ground under acetone produced fine needles and fluffy aggregates which resembled chrysotile asbestos and had elicited some earlier interest¹. Evidence indicated tetragonal symmetry and despite several attempts no report of a successful structure solution has appeared. Indeed, the structure analysis proved to be a challenge, and revealed $^{1/2}[\text{Si}_8\text{O}_{20}]$ tubular columns and $[\text{Pb}_2\text{OPb}_4\text{O}_{24}]$ clusters, the latter consisting of six Pb^{2+} cations situated on the vertices of a compressed octahedron. A novel feature is the occurrence of disordered (Pb^{2+} , K^+) as a 'solid solution', the $\text{Pb}-\text{K} = 0.59 \text{ \AA}$ separation being a consequence of the $6s^2 \text{ Pb}^{2+}$ lone pair acting on circumjacent bond pairs. In our initial experience, best convergences yielded the reliability index $R \sim 0.20$. Unit cell parameters, space group and other structure cell criteria in Table 1 show good agreement between the present study and an earlier report² on KPS and isostructural $\text{Pb}_2\text{Pb}_4\text{Si}_6\text{Al}_2\text{O}_{21}$.

Our data set, on a crystal which was initially checked with assorted precession photographs and yielded condensed X-ray symbol $\text{I4}/***$, included 421 unique reflections for refinement. The data set was collected with an Enraf Nonius CAD-4 automated diffractometer utilizing graphite monochromator and $\text{MoK}\alpha_1$ radiation. All 3,326 reflections for $2\theta \leq 60^\circ$ were collected, and each was corrected for absorption based on an empirical ψ -scan, and symmetry-equivalent reflections were averaged. Unit cell dimensions (Table 1) were obtained by least-squares refinement of 25 reflections distributed throughout reciprocal space.

The final crystal structure was deciphered quite serendipitously. Three-dimensional Patterson maps quickly revealed the Pb-Pb vectors, and attempts were made to locate the remaining Pb-X (X = K, Si, O) vectors through models constructed in space group $\text{I4}/mmm$; and its subgroups I4mm , I42m , I4m2 and I422 . A $\text{Pb}(1)$, $\text{Pb}(2)$ and K combination was introduced to a least-squares refinement, but the $\text{Pb}(2)$ -K site distance was

Fig. 1 Structure diagram of $\text{Pb}_2\text{O}(\text{Pb}_2\text{K}_2)[\text{Si}_8\text{O}_{20}]$ down $[001]$. The silicate tubes appear as stippled tetrahedra. Oxygens are located at solid disks, Pb atoms at squares and K atoms at crosses. Note O(1) superimposes on Pb(1) in this projection. Pb(2)–O bonds (solid) and Pb(1)–O bonds (dashed) are shown around the origin of the cell, K–O bonds (dot-dash) around body centre at $(\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$. Individual bond distances (in Å, errors < 0.01 Å) and polyhedral averages (in brackets) are shown adjacent to their geometric elements. Heights of atoms along c are given in fractional coordinates for their asymmetric unit.

only 0.6 Å. Surprisingly, $R = 0.10$. It then became clear that an apparent solid solution existed between Pb(2) and K. From that model, all other atoms could be located on a Fourier synthesis, which was based on space group $I4/mmm$. Continued coordinate parameter refinement followed by full-matrix anisotropic thermal vibration parameter refinement led to $R = 0.034$. Atom coordinate parameters from the final refinement appear in Table 2. We are forced to conclude that Pb(2) and K are coupled, both Pb(2) and K sites each half-populated about a centroid at $(\frac{1}{2}, \frac{1}{2}, 0)$. As we discuss below, these results are a consequence of an effect on solid solution from the interaction of $6s^2$ Pb $^{2+}$ lone pair with neighbouring bond pairs. The compound is a plumbous potassium oxysilicate, more specifically $\text{Pb}_2\text{O}(\text{Pb}_2\text{K}_2)[\text{Si}_8\text{O}_{20}]$.

KPS is structurally related to some other well-defined arrangements. Figure 1 shows K–O, Pb–O bonds and $[\text{Si}_8\text{O}_{20}]$ polyhedral linkages; Bond distances and polyhedral averages are also presented. Two distinct regions or fundamental building blocks can be discerned which, when isolated, show a direct relationship to some other structure. The first region is the $[\text{Si}_8\text{O}_{20}]$ column or tube which runs parallel to the c -axial direction. Perhaps the simplest way to describe this silicate tube is by corner-linked condensation of $[\text{Si}_2\text{O}_7]$ sorosilicate units, the tube generated by the 4_2 -screw operation parallel to the c -axis implicit in space group $I4/mmm$. This motif occurs in several distinct structure types, the simplest³ being narsarsukite, $\text{Na}_4\text{Ti}_2\text{O}_2[\text{Si}_8\text{O}_{20}]$. In the structure we report, the tube is more rigid, constrained by the presence of additional mirror planes which are normal to the a_1 and a_2 axial directions. The second region was an unexpected surprise. It is centred on O(1) at the

origin of the unit cell, and has local stoichiometry $\text{Pb}(1)_2\text{O}(\text{Pb}(2)_4\text{O}_{24})$, selecting the Pb end-member. A $\text{Pb}(1)_2\text{Pb}(2)_4$ cation cluster surrounds O(1), and is a compressed octahedron, with eight apical Pb(1)–Pb(2) = 3.36 Å and four equatorial Pb(2)–Pb(2) = 3.56 Å, with an average of Pb–Pb = 3.43 Å. From the individual polyhedral bond distances, it is evident that the $6s^2$ lone electron pairs in Pb $^{2+}$ are situated on the outside of the $[\text{Pb}_6]$ octahedron in KPS. Note that the interatomic separation⁴ in Pb metal (face-centred cubic, f.c.c.) is 3.500 Å. This does not imply metallic Pb–Pb bonds in KPS, since the intervening anions and Pb–O bonds in the silicate must be included.

The Pb(2) and K sites, their half-occupancy the source of difficulty in structure solution, have separation K–Pb(2) = 0.59 Å. Decomposing the cluster into its polyhedral components, the $\text{Pb}(1)\text{O}(1)\text{O}(2)_4$ or $\text{Pb}(1)\text{O}_5$ defines a square pyramid of oxygen atoms coordinated to Pb(1). Alternatively, it can be described as an octahedron about Pb(1) with one vertex representing the lone electron pair (symbolized ψ) from $6s^2$ Pb(1) $^{2+}$. The Pb(1) atom is displaced 0.59 Å away from the equator of the $\text{Pb}(1)\text{O}_5\psi$ octahedron and towards the direction of the lone pair. Similar coordination polyhedra have been reported in several structures, although refinements which involve at least one heavy metal in an oxide matrix were usually inferior. A good example is the $\text{PbO}_4\psi$ polyhedron in the structure of tetragonal PbO or litharge, and refined from neutron diffraction data⁵. The shortest distance, Pb(1)–O(1) = $2.228(1)$ Å, opposes the assumed centroid of the lone pair. In litharge, the Pb atom is displaced 1.19 Å away from the equator and towards the direction of the lone pair. The average Pb–O distance in PbO_4 for litharge, a square pyramid with Pb as the apex, is 2.31 Å, significantly shorter than the 2.42 Å average for KPS. The short basal O–O = 2.80 Å separation in litharge contrasts with the tetragonal base distance O(2)–O(2) = 3.26 Å in KPS. These shorter distances in litharge are probably based on differences in oxygen coordination number about Pb(1), being 4 for litharge and 5 for KPS.

A large family of structures involves components Pb–X–O–H–Cl where X = Cu $^{2+}$, Mn $^{2+}$, Bi $^{3+}$, Sb $^{3+}$, As $^{3+}$, and so on, and many are based on similar structural principles. One well-refined structure⁶ includes diabolite, $\text{Pb}_2\text{Cu}(\text{OH})_4\text{Cl}_2$, with tetragonal space group $P4mm$ and one formula unit in the structure cell.

The polyhedron of interest is $[\text{Pb}^{2+}\text{O}_4\text{Cl}_4]$ which is a distorted square antiprism. There exist $4\text{Pb}-\text{OH}=2.48$ and $4\text{Pb}-\text{Cl}=3.32$ Å averages. Electing $r=1.40$ Å for $^{[6]}\text{O}^{2-}$, $r=1.81$ Å for $^{[6]}\text{Cl}^-$ and $r=1.29$ Å for $^{[8]}\text{Pb}^{2+}$, the calculated averages are $\text{Pb}^{2+}-\text{O}=2.69$ Å and $\text{Pb}^{2+}-\text{Cl}=3.10$ Å, effective averages larger and smaller, respectively, than the experimental averages for diabolite. This was noted in the earlier study which further supports the interaction between the $6s^2$ Pb^{2+} lone pair with the enveloping bond pairs. It requires that the centroid of the lone electron pair is towards the direction of the plane of the Cl^- ions, foreshortening the opposing $\text{Pb}^{2+}-\text{OH}^-$ distances and lengthening the adjacent $\text{Pb}^{2+}-\text{Cl}^-$ distances with respect to the effective averages. An analogous relation can be found for $\text{Pb}(1)\text{O}_5\psi$ in KPS where $4\text{Pb}(1)-\text{O}(2)=2.47$ Å and $1\text{Pb}(1)-\text{O}(1)=2.23$ Å. If the centroid of the lone pair is postulated to oppose O(1) in KPS; then the short $\text{Pb}(1)-\text{O}(1)$ distance and the absence of $\text{Pb}^{2+}-\text{O}$ bonds on its opposing side can be understood. It is immediately apparent that the average for the Pb ion stripped of all its valence electrons, $^{[6]}\text{Pb}^{4+}-\text{O}=2.18$ Å from the same tables⁷, is not far removed from $\text{Pb}(1)-\text{O}(1)$ in KPS. Increase in average distances for coordination polyhedra of increasing order has been explained adequately elsewhere⁸. Similarly, displacement of a metal with a lone electron pair from the equator of a coordination polyhedron has electrostatic origins in the interaction implicit on a cation with a lone pair of electrons and the circumjacent bond pairs⁹.

The remaining polyhedron in the second region is a distorted monocapped cube, or $\text{Pb}(2)\text{O}_9$. The average distance is $\text{Pb}(2)-\text{O}=2.93$ Å, but the range in polyhedral distances is considerable, from $\text{Pb}(2)-\text{O}(2)=2.49$ Å to $\text{Pb}(2)-\text{O}(3)=3.47$ Å. We propose that the locus of the lone pair is on $\text{Pb}(2)$ opposite the $\text{Pb}(2)-\text{O}(1)$ bond, the considerable distortion in polyhedron and bond distances being due to the effect from interaction of a lone pair with the surrounding bond pairs. Further evidence for this interaction can be obtained from the same structure by selecting the site centroid of the KO_9 polyhedron associated with the purported $[\text{K}, \text{Pb}(2)]$ solid solution. The distances range from $\text{K}-\text{O}(2)=2.74$ Å to $\text{K}-\text{O}(3)=3.23$ Å with an average $\text{K}-\text{O}=3.00$ Å, a range of only 0.49 Å compared with a range of 0.98 Å for $\text{Pb}(2)-\text{O}$. This is a rare case where a cation with a lone pair of electrons in the valence shell can be directly compared with a cation where all valence electrons are stripped away in the same polyhedral environment which, in effect, constitutes a structural solid solution (compare with isostructural $\text{Pb}_2\text{Pb}_4\text{Si}_6\text{Al}_2\text{O}_{21}$).

Another feature is the similarity of the cluster in the second region to the structure of hyalotekite, a complex lead-barium-calcium-borosilicate-fluoride¹⁰. This compound is triclinic, but its cell is pseudo-tetragonal, with $a \sim 11.1$ Å, $c \sim 10.3$ Å and possesses two formula units in the cell. A weak structural relationship occurs between KPS and hyalotekite. Writing the formulae in sequence hints at this relationship.

KPS $\text{Pb}_2\text{O}(\text{Pb}_2\text{K}_2)$ $[\text{Si}_8\text{O}_{20}]$ $\text{Pb}-\text{K}=0.59$ Å
Hyalotekite $\text{Ca}_2\text{F}(\text{Pb}_2\text{Ba}_2)$ $[\text{Be}_{0.5}\text{B}_2\text{Si}_{9.5}\text{O}_{28}]$ $\text{Pb}-\text{Ba}=0.46$ Å

In both structures, an apparent solid solution exists between a cation possessing a lone pair and a cation with a closed shell.

The KPS structure invites a simple experiment. The effect on a solid solution from interaction of a lone pair and neighbouring bond pairs with respect to temperature is unknown. Even the problem of solid solution between a cation possessing a lone pair (such as Pb^{2+}) and a cation stripped of all its valence electrons (such as K^{1+}) is not understood. We plan to study the crystal structure of KPS at elevated subsolidus temperatures to explore in more detail the bond distances and behaviour of the anisotropic thermal vibration ellipsoids through the thermal effect on the $\text{Pb}(2)-\text{K}$ site separation. Finally, since the lone electron pairs about Pb^{2+} are evidently circumjacent to the second aforementioned structural region and since the first region is a silicate tube, the curious appearance of fluffy fibrous material on grinding clear crystals suggests a pressure effect on the interaction between a lone pair and circumjacent bond pairs. Bond length, bond angle and solid solution dependencies on temperature and pressure would be most informative.

We thank G. E. Brown and G. V. Gibbs for donation of the KPS sample. Portions of this study were supported by the NSF-EAR-84-08164.

An interhemispheric comparison of the concentrations of bromine compounds in the atmosphere

S. A. Penkett*[‡], B. M. R. Jones*, M. J. Rycroft[†] & D. A. Simmons[†]

* Atomic Energy Research Establishment, Harwell, Oxfordshire OX11 0RA, UK

[†] British Antarctic Survey, Cambridge, CB3 0ET, UK

At least seven organic bromine compounds have been positively identified in the atmosphere^{1,2} (CH_3Br , CH_2Br_2 , CHBr_3 , CH_2BrCl , CF_3Br , CF_2BrCl and $\text{C}_2\text{H}_4\text{Br}_2$) and others have been observed in coastal seawater samples ($\text{C}_2\text{H}_5\text{Br}$, $\text{C}_3\text{H}_7\text{Br}$ and CHBr_2Cl) (S. A. P. and R. A. Rasmussen, unpublished data). The atmospheric chemistry of bromine compounds has considerable consequence in the stratosphere, where bromine acts as a more efficient catalyst than chlorine in removing ozone^{3,4}. Several

[‡] Present address: University of East Anglia, Norwich NR4 7TJ, UK.

bromine compounds also fulfil an important role in the geochemical cycling of the element through the troposphere⁵. Here we present measurements of four bromine compounds (CF_3Br , CH_3Br , CH_2Br_2 and CHBr_3) over a large latitudinal range (40°N to 75°S). These data suggest that the major source of bromine in the atmosphere could be bromoform (CHBr_3), probably emitted from the ocean and with a short lifetime due to photolysis. Our data also suggest that the major emission of methyl bromide (CH_3Br), and hence most bromine entering the stratosphere, will be anthropogenic.

The specific sources of many bromine compounds are unknown, but are either anthropogenic or natural, with ocean chemistry and volcanic activity being obvious choices for the latter. The atmospheric lifetimes of the individual molecular species are likely to differ by many orders of magnitude, depending on the reaction rate with hydroxyl radicals or the photolytic destruction rate.

One way to categorize the source type and reactivity is to collect information on the latitudinal and longitudinal variation of the concentration of these compounds, in particular, to determine whether there is a substantial difference in concentration between Northern and Southern Hemispheric air samples. This is because the vast majority of anthropogenic sources are situated in the Northern Hemisphere and the interhemispheric transfer time is quite long (1–4 yr)^{6,7}.

Measurements of this type have been made at Harwell on air samples collected by the British Antarctic Survey (BAS) whose ships regularly traverse the Atlantic and Southern Oceans from about 50°N to 75°S on route from the UK to Antarctica. The samples were collected using a cryogenic trapping technique originally devised by Rasmussen⁸. Air was sampled on the bow of the BAS ships *RRS Bransfield* through a 10-ft length of steel pipe, which protruded out from the plating, and the sampling time was typically 10 min. The samples were only collected when the wind was on the bow or from a non-contaminating quarter, so the potential for contamination from the ship was very small. Typically 50 l of air were collected in each of the stainless steel sample bottles (volume 1.6 l), which were made to high specifications by Rasmussen. The properties of these containers with respect to contamination and decay of many trace gases have been studied extensively. Almost all trace gases were found to be stable at the high pressures (~ 450 p.s.i.) resulting from the sample collection process, when the air contained amounts of water vapour typical of surface samples. The wind direction was recorded at the time of sampling. No air mass trajectory calculations have been made due to difficulty in obtaining meteorological data.

In 1982, the ship sailed from Southampton to Cape Town, South Africa, passing the Canary and Ascension Islands along standard steamship routes and then to Antarctica. In 1983, the ship sailed from Southampton to Rio, Brazil, passing the Canary Islands and about 100 km east of the Cape Verde Islands along the steamship route and then on to Antarctica. The samples collected as far as Cape Town and Rio were air-freighted to London and analysed at Harwell within 6 weeks of collection. The samples collected farther south arrived back in England up to 6 months after collection. No marked difference in trace gas concentrations could be observed due to the different storage times.

The samples were analysed at Harwell for a large range of trace gases including halocarbons, hydrocarbons and sulphur compounds. In the case of the bromine compounds, which were the subject of this investigation, analysis was made using a highly sensitive gas chromatograph/mass spectrometer (GC/MS) combination developed especially for atmospheric trace gas measurements⁹. Before injection into the GC the air sample was enriched using a procedure very similar to that described previously¹⁰. This requires condensation of the gaseous air to liquid and removal of the permanent diluent gases under vacuum at liquid nitrogen temperature. The calibration procedure involved a static dilution technique which has been described in detail elsewhere¹¹. The detection limit was

~ 0.5 p.p.t.v. (parts per 10^{12} by volume) for CH_3Br , 0.2 p.p.t.v. for CH_2Br_2 and CF_3Br and ~ 0.1 p.p.t.v. for CHBr_3 . The precision of the analysis and sampling procedure was $\sim 10\%$ for all four compounds as the largest error arose in estimating the volume used in the analysis stage.

Data for the variation of concentration with latitude are shown in Fig. 1 for CH_3Br , CH_2Br_2 , CHBr_3 and CF_3Br . In the case of methyl bromide (CH_3Br), (Fig. 1a) there is a clear reduction in concentration between the two hemispheres, such that the average concentration in the Northern Hemisphere (NH) is 15.4 ± 1.9 p.p.t. and that in the Southern Hemisphere (SH) is 10.6 ± 0.9 p.p.t. There is also more scatter in the limited amount of Northern Hemisphere data while the variation in the southern data is very close to the limits of precision for the GC/MS system ($\sim 10\%$). A similar interhemispheric gradient has been observed previously¹² but the concentrations observed in both hemispheres were higher.

Methylene dibromide (CH_2Br_2) (Fig. 1b) also shows a marked hemispheric difference in concentration (NH = 2.70 ± 0.59 p.p.t.v., SH = 1.58 ± 0.26 p.p.t.v.) with again less variation in the Southern Hemisphere. The bromoform (CHBr_3) data (Fig. 1c) are much more scattered than either the CH_3Br or the CH_2Br_2 data. Although there is a tendency for the Northern Hemisphere concentrations to be higher, the mean interhemispheric difference is within the scatter of the data. The values for the mean and standard deviation are NH = 0.85 ± 0.44 p.p.t.v., when the value of 5.96 p.p.t.v. at 20°N is omitted, and SH = 0.58 ± 0.30 p.p.t.v. with the inclusion of the equatorial value of 0.88 p.p.t.v. These are both valid procedures since; first, the CHBr_3 concentration in the 20°N sample was elevated far above the average whereas none of the other trace gases measured showed such an elevation, and second, other trace gases such as ethane and some saturated hydrocarbons in the equatorial sample gave results typical of the Southern Hemisphere. There is no evidence that the high value at 20°N was associated with long-range transport of a plume of anthropogenic pollutants, because other trace gases indicative of pollution were present at levels similar to the average for the Northern Hemisphere samples. The slightly higher concentrations of CHBr_3 at 75°S in 1982 and 50°S in 1983 cannot be explained in terms of anthropogenic emissions. These data could mean that CHBr_3 has oceanic sources in both hemispheres and that it is more reactive in the atmosphere than are the mono- and di-bromo-substituted methanes. The CHBr_3 data contrast with those for CF_3Br (Fig. 1d) which show a very small gradient north and south on the 1982–83 voyage and a variability well within the limits of precision of the measurements (NH = 1.15 ± 0.05 p.p.t.v., SH = 1.06 ± 0.09 p.p.t.v.). CHBr_3 and CH_2Br_2 have been identified in coastal seawater (S. A. P. and R. A. Rasmussen, unpublished data).

The different variability in the concentration of the four molecules is associated with different source distributions and reactivity. The simplest behaviour is that of CF_3Br (CFC-13B1) which is used as a flame retardant and is unlikely to have any natural sources. The molecule is mostly emitted into the atmosphere in the Northern Hemisphere and it has no significant tropospheric sinks. However, it is removed in the stratosphere by photolysis, as shown by measurements of its vertical profile up to 25 km (ref. 13). The small interhemispheric gradient is very similar to that of CFC 11 and 12, which have been growing in concentration at a rate close to $5\% \text{ yr}^{-1}$. A similar growth rate is therefore anticipated for CF_3Br . This compound was originally detected in the atmosphere in 1980 and its concentration then was estimated to be about 0.7 p.p.t.v. (ref. 10). Unfortunately, this was not a precise estimate and thus no absolute growth rate can be ascertained from our data at present.

CH_3Br is extensively used as a fumigant and annual production in 1972 was estimated to be about 300,000 tons, a quarter of which (75,000 tons) was probably emitted to the atmosphere¹. It has also been proposed that the ocean is a major source, as in the case of methyl chloride and methyl iodide^{13,14}.

If it is assumed that CH_3Br is mostly removed from the

atmosphere by reaction with hydroxyl radicals in the troposphere, then the present data can be used to estimate the size of the annual input. A recently calculated value of the global average hydroxyl concentration is 4×10^5 molecules cm^{-3} (ref. 15); the atmospheric burden of CH_3Br is about 2.26×10^5 tons according to our data. These data require an annual input of 90,000 tons assuming removal only by hydroxyl radical chemistry with a rate constant of 3.2×10^{-14} cm^3 per molecule per s at 280 K (ref. 15). This is only slightly higher than the estimate³ of anthropogenic atmospheric emission made in 1972 of 75,000 tons, suggesting either that the ocean makes a relatively small contribution to the atmospheric burden of CH_3Br or that our rather simple chemistry is incorrect. An independent check on the chemistry can be made by comparing the methyl bromide levels in the two hemispheres. Assuming only a Northern Hemisphere source for CH_3Br which is transferred to the Southern Hemisphere with a relaxation time of 400 days, then the global average hydroxyl concentration required to account for the data is 3.6×10^5 molecules cm^{-3} , assuming all reactions take place at 280 K. The chemistry, therefore seems to be consistent and this leaves a problem with the oceanic source of CH_3Br . An estimate made recently¹² suggests that 300,000 tons of CH_3Br are emitted annually from the ocean. This would far outweigh the anthropogenic emission of CH_3Br and would argue for the globally-even distribution in concentration, observed for CH_3Cl (ref. 12), which has a similar removal rate from the atmosphere by hydroxyl radicals¹⁶. The global average hydroxyl concentration is an uncertain quantity and a larger total emission of methyl bromide into the atmosphere can be allowed, but the weight of evidence does not favour a large natural source.

Our interpretation of the data, therefore, suggests that the predominant source of CH_3Br in the atmosphere is anthropogenic rather than natural. This has important consequences for stratospheric ozone chemistry. It has been assumed previously that the stratospheric burden of bromine was mainly natural in origin and that any reduction in ozone produced by its presence was not a recent phenomenon¹⁰. This assumption is now questionable, and we suggest that stratospheric bromine chemistry should be examined more carefully in the context of possible effects of increased anthropogenic emissions.

The degree of variation in concentration suggests that both CH_2Br_2 and CHBr_3 are quite reactive in the troposphere, more so than CH_3Br and much more so than CF_3Br . They may have a mixture of sources since the CH_2Br_2 and CHBr_3 concentrations have been observed to increase during pollution incidents in the Arctic¹. Also, GC/MS studies of sea water containing different types of seaweed collected at a coastal site in southern England, show evidence for the presence of many different bromine compounds. These included $\text{C}_2\text{H}_5\text{Br}$, $\text{C}_3\text{H}_8\text{Br}$, CH_2BrCl , CHBr_2Cl and at least an order of magnitude greater quantities of CH_2Br_2 and CHBr_3 (S. A. P. and R. A. Rasmussen, unpublished data). It seems possible from the following calculations that CHBr_3 is the most important natural vector for gaseous bromine in the atmosphere and that CH_2Br_2 also has substantial natural sources. Their chemical lifetimes are unknown at present because of lack of published data either on rates of removal by hydroxyl radicals or on their photochemistry. However, the rates of reaction of the bromine compounds CH_3Br and $\text{BrCH}_2\text{CH}_2\text{Br}$ with hydroxyl radicals are very similar to those for their chlorine analogues. It is not unreasonable to assume, therefore, that to a first approximation, the rates for CH_2Br_2 and CHBr_3 are also similar to those for their chlorine analogues, for which published data exist: $k_{280\text{K}} = 1.128 \times 10^{-13}$ cm^3 per molecule per s for CH_2Cl_2 and 8.28×10^{-14} cm^3 per molecule per s for CHCl_3 (ref. 16). These rates should lead to a substantial interhemispheric gradient such as that observed for CH_2Cl_2 in our own unpublished data, where Southern Hemisphere values are only a quarter of the Northern Hemisphere values. The concentration distribution shown in Fig. 1 thus argues strongly for substantial sources of both CH_2Br_2 and CHBr_3 in the Southern Hemisphere, which must surely be natural rather than anthropogenic.

Fig. 1 Longitudinal transects of the concentrations of four bromine compounds: a, CH_3Br ; b, CH_2Br_2 ; c, CHBr_3 ; d, CF_3Br . \circ , 1982 voyage via Cape Town; \times , 1983 voyage via Rio; $+$, values collected on other experiments.

The case for natural sources of CHBr_3 is emphasized when a consideration is made of its potential atmosphere photochemistry. No published absorption spectrum could be found but some preliminary measurements were made at Harwell using a diode array spectrometer in conjunction with R. A. Cox. The absorption maximum occurs at a wavelength of 221 nm, where $\sigma = 5.51 \times 10^{-18} \text{ cm}^2$ per molecule and a significant overlap occurs in the region of tropospheric solar flux (305–320 nm). Assuming a quantum yield of unity, the atmospheric lifetime of CHBr_3 due to tropospheric photolysis could be as low as 2 weeks. This would require an annual emission in the region of 10^6 tons, which almost certainly exceeds the anthropogenic emissions many times over and makes CHBr_3 the most significant source of bromine released into the atmosphere. It is unlikely, though, that much CHBr_3 would penetrate into the stratosphere with a tropospheric lifetime this short.

Finally, there appear to be a substantial number of bromine compounds present in sea-surface waters that can find their way into the atmosphere. This indicates the presence of a rich bromine chemistry and mixed chlorobromo chemistry in the ocean that merit investigation in detail. The chemical behaviour of the bromine atoms released in both the troposphere and the stratosphere also needs study.

This work was carried out with funds provided by the British Antarctic Survey (BAS). We particularly thank the many individuals at BAS who assisted in the collection of clean air samples, and also Dr R. A. Cox of Harwell who obtained the absorption spectrum for CHBr_3 .

Pyroxene solid solution in garnets included in diamond

Rory O. Moore & John J. Gurney

Department of Geochemistry, University of Cape Town, Private Bag, Rondebosch 7700, South Africa

In what proved to be a temporary phase of trial mining of the Monastery Mine kimberlite pipe, South Africa, we recently had a brief opportunity to characterize the mineral inclusions in diamonds from this locality. The usefulness of such studies in elucidating mantle processes has already been demonstrated^{1–3}. We describe here garnets included in diamonds which have a unique range of compositions. They are interpreted as representing the first natural occurrence of garnet hosting a component of pyroxene in solid solution. Their discovery fulfils predictions based on successful laboratory experiments in which pyroxene was dissolved in garnet at very high pressures (50–180 kbar)^{4–6}. As this solid solution is accompanied by an increase in density, such results have both geophysical and chemical implications for the structure

Fig. 1 Plot of atomic Na against atomic Si for 12 oxygens. Group A represents garnets of similar composition to eclogitic diamond inclusion garnets worldwide^{1–3,12–16}. Group B represents garnets interpreted to host a component of pyroxene in solid solution. Δ , Group A garnets; \diamond , group B garnets.

of the mantle. In addition, the pressures inferred are higher than generally proposed for mantle minerals sampled by kimberlites. Recent work has demonstrated that at least some inclusion-bearing diamonds have been derived from Archaean lithosphere⁷. The Monastery garnets in diamonds may indicate that the old lithosphere was very thick^{8,9}. Alternatively, if they have an asthenospheric origin, they may prove particularly interesting because of their different source.

Monastery Mine is situated near the border between South Africa and Lesotho, close to the inferred eastern margin of the Kaapvaal Craton. It was an inviting target for a study of mineral inclusions in diamonds because it is geographically well separated from the established kimberlite diamond mines in southern Africa and because it is a kimberlite with an abundance of fresh xenoliths and xenocrysts of mantle rocks and minerals to which the inclusions and hence the diamonds might be related. The general geology of Monastery has been described elsewhere¹⁰.

In this study, 131 inclusion-bearing diamonds in the size range $-9+5$ (ref. 11) were selected from 4,600 carats of general production. The diamonds are <3 mm in largest dimension and average ~ 0.12 carats per stone. After careful visual inspection and rigorous cleaning, the inclusions were liberated from the diamonds by mechanical crushing in an enclosed steel cracker. The individual inclusions, usually between 75 and 250 μm in longest dimension were mounted in epoxy resin on glass slides and polished. Mineral compositions were determined by means of a Cameca Camebax microanalyser, using standards of essentially similar composition to the unknowns and an on-line ZAF correction procedure. Analyses are believed to be accurate to $\pm 1\%$ relative and have been checked at two independent microprobe laboratories.

The minerals found as inclusions in diamonds from the Monastery Mine kimberlite are almost entirely of an eclogitic paragenesis. Fifty-six eclogitic garnets have been analysed. Each analysis represents an average of at least five individual spots either on a single inclusion or several inclusions from the same diamond. Two distinct populations of eclogitic garnets are present in the diamonds (Fig. 1). One group (termed group A) consists of 10 garnets which have compositions similar to those described from diamonds worldwide^{1–3,12–16}. They have Na_2O concentrations which range from 0.04 to 0.25 wt%, variable quantities of FeO , MgO and CaO typical of eclogitic garnets included in diamond, and SiO_2 and Al_2O_3 present in normal stoichiometric proportions, namely 39.0–42.2 wt% SiO_2 and 20.19–23.06 wt% Al_2O_3 (Fig. 2). The second group (group B) consists of 46 garnets that form a related suite of compositions which have never been reported before. Particularly extreme concentrations of Si and Al range to as high as 47.43 wt% SiO_2 and as low as 11.29 wt% Al_2O_3 (Fig. 2). Note that the low Al_2O_3 values are not supported by high Cr_2O_3 concentrations as occurs for peridotitic garnets, the maximum chrome concentration in

Values given are for diamonds from Monastery Mine (analyses 1–5), while analysis 6 represents a garnet hosting a component of pyroxene in solid solution, synthesized experimentally at 146 kbar and 1,200 °C (ref. 6)

* M = Mg + Fe + Ca + Na.

these garnets being 0.37 wt% Cr₂O₃. Sodium can be present in extremely high concentrations, ranging from 0.14 to 1.03 wt% Na₂O (Fig. 2). Two garnets of similar composition to the group B garnets were reported from Jagersfontein by Tsai *et al.*¹⁴ but they did not comment on their unusual chemistry.

Representative analyses of both groups of garnets together with an analysis of an experimentally synthesized garnet⁶ are presented in Table 1. At first glance the extreme compositions in group B resemble amphibole compositions. However, samples spanning the compositional range of the garnets have been analysed by X-ray diffraction using a 57.4-mm Gandolfi camera and Co K α radiation. Extremely high-quality photographs were obtained and all unequivocally confirm a garnet structure for both groups of garnets. Cell parameters (a_0) calculated according to the equation

$$a_0^2 = (h^2 + k^2 + l^2)d_{hkl}^2$$

where a_0 is the unit cell parameter, hkl is the Miller index for a crystal plane, and d is the d -spacing of the crystal, and using the (10, 4, 0) reflection, range between 11.564 and 11.629 Å, which correlates well with cell parameters for pyrope, almandine and grossular (11.455, 11.53 and 11.85 Å respectively).

The pyroxene and garnet mineral families have closely related basic chemical formulae in that both possess cation to oxygen anion ratios of 2:3. Under appropriate conditions of pressure and temperature, small quantities of garnet may be taken into solid solution in pyroxenes^{17,18}. As pressure is increased, however, this solid solution breaks down into low-alumina pyroxene plus exsolved garnet¹⁹. Experimental evidence has demonstrated that the inverse of this reaction is also possible, namely the solution of pyroxene in garnet^{4–6,19,20}, and because of the large density difference involved, this reaction would also be expected to be strongly pressure dependent. Ringwood²⁰ demonstrated that as pressure increases, the solubility of pyroxene in garnet increases. Akaogi and Akimoto⁵ studied pyroxene–garnet solid solution equilibria over a wide range of temperatures and pressures in Mg- and Fe-rich systems. They found that the solubility of enstatite (MgSiO₃) in pyrope (Mg₃Al₂Si₃O₁₂) increases gradually from 60 to 140 kbar and then increases suddenly in the pressure range 140–175 kbar,

resulting in the formation of a homogeneous garnet with a composition Mg₃(Al_{0.8}Mg_{0.6}Si_{0.6})Si₃O₁₂. Similar results were obtained for the ferrosilite–almandine system. The results of the experimental studies in simple systems have been verified and extended by Akaogi and Akimoto⁶, who successfully demonstrated a continuous increase in the solubility of pyroxene in garnet in a natural garnet lherzolite assemblage (PHN-1611) in the pressure range 45–205 kbar at temperatures of 1,050 and 1,200 °C. On the basis of these studies, Akaogi and Akimoto^{5,6} predicted that pyroxene would begin to dissolve in garnet at depths of 150 km in the upper mantle and that this would be manifested by an appreciable increase in the number of Si ions over the ideal value of 3 for 12 oxygens, indicating accommodation of Si ions in octahedral coordination.

The group B diamond inclusion garnets at Monastery are interpreted in the light of the above experimental data. The number of Si ions for 12 oxygens in these garnets ranges from 3.046 to 3.429 (Fig. 1, Table 1), necessitating the existence of some Si in octahedral coordination. It is suggested that the group B garnets host a component of pyroxene in solid solution, an interpretation strongly supported by a comparison of the compositions of the group B garnets and the experimentally synthesized garnets⁶ (see Table 1, in particular analyses 4 and 6). Further evidence in support of this interpretation is the fact that the value of M (M = Mg + Fe + Ca + Na) in the group B garnets increases concomitantly with the increase of Si from 3.0 (see Table 1). Although M is not a good indicator of the presence of pyroxene in solid solution in garnet compared with Si, an increase of both M and Si is required to form garnet solid solution with pyroxene components (since pyroxene ~ Si + M).

Note that the Ca-rich garnets tend to have lower Si contents than the magnesian garnets, indicating that they have less pyroxene in solid solution. This is consistent with the data of Akaogi and Akimoto⁶, who found that systematically higher pressures are required for the solution of pyroxene in garnet in Ca-rich systems than in Fe- and Mg-rich systems. In addition, the Fe-Ca-rich group B garnets show extreme enrichment in Na and lesser depletions of Al than the magnesian group B garnets. This may be due to a similar effect to that described for inclusions in diamonds from Orapa³, where the composition of the pyroxene molecule in equilibrium with garnet changes with garnet composition. The major change is an increase in the jadeite molecule at the expense of diopside as iron and calcium in garnet increases. Solid solution of such pyroxenes in eclogitic garnets would be expected to produce the trends noted above.

Sobolev and Lavrent'ev²¹ suggested that elevated concentrations of Na in garnet may be correlated with high pressure. They proposed that Na enters the garnet structure according to the equation

thereby requiring some Si to be present in octahedral coordination. Thompson²² reported 0.06–0.57 wt% P_2O_5 in garnets synthesized from anhydrous basaltic melts at 18–45 kbar and 1,200–1,450 °C and proposed a coupled substitution between Na–P and Ca–Si. He points out that since the sum of atomic radii of Na and P is less than that of Ca and Si, the substitution of an Na–P couple into the garnet structure would be enhanced by high pressure. Bishop *et al.*²³ favour the idea that Na in garnets from peridotites and eclogites can be explained by substitutions of the type

without the need to invoke octahedral Si.

The group B garnets have been carefully analysed for P and found to have <0.01 wt% P_2O_5 . The coupled substitution between Na–P and Ca–Si is thus not feasible in this case. The coupled substitution between Ca–Al and Na–Si proposed by Sobolev and Lavrent'ev²¹ is also not possible, because of the existence of a negative correlation between Si and Na in these garnets (Fig. 1). The excellent negative correlation observed between Si and Al (Fig. 3), however, probably indicates that the substitutional scheme proposed by Akaogi and Akimoto⁶ to account for the compositions of their experimentally synthesized garnets (for example, Table 1, analysis 6) is also applicable to these garnets. The scheme involves the substitution of two Al^{3+} ions in the octahedral sites of the garnet structure by M^{2+} and Si^{4+} ions from the pyroxene structure ($\text{M}^{2+} = \text{Mg}^{2+}$, Fe^{2+} and Ca^{2+}). Na may be accommodated in the eight-coordinated dodecahedral site, as suggested by Sobolev and Lavrent'ev²¹.

The highest reported sodium value in an eclogitic diamond inclusion garnet was until recently 0.26 wt% Na_2O (ref. 21), but Hall and Smith²⁴ have reported Na-rich eclogitic garnets from Argyle, the highest concentration being 0.52 wt% Na_2O . Although they also failed to find a correlation between Na, Ti and P, appreciable P_2O_5 was detected and there is no evidence in the published analyses for excess silica or a deficiency of aluminium. Their garnets do not, therefore, appear to be like those described here.

The discovery of garnets from the upper mantle hosting pyroxene in solid solution and having Si in octahedral coordination is extremely important in view of current petrological modelling of the mantle. A controversial issue is whether the eclogite to garnetite transition is responsible for the 400-km seismic discontinuity^{25–27}. Our data show that the dissolution of pyroxene in garnet does occur in the upper mantle and, therefore, strengthens the evidence for the feasibility of the garnetite transition.

It is generally believed that diamonds have crystallized at depths >150 km (ref. 1), but the temperatures of equilibration calculated for coexisting diamond inclusion pairs^{1,12,13,24} are generally so low that origins deeper than 200 km have not been suggested. Palaeogeothermal reconstructions^{28,29} based on xenolith mineral compositions from kimberlite terminate at similar depths, which could mark the lithosphere–asthenosphere boundary. The group B garnets range to compositions showing extensive pyroxene solid solution in garnet, which is not seen in other mantle-derived garnets. As this solid solution is a predominantly pressure-dependent reaction, it seems likely that the group B garnets have an extremely deep origin. Based on experiments by Akaogi and Akimoto⁶ on a natural garnet lherzolite, pressures well above 100 kbar are possibly required; for example, garnet 6 in Table 1 was synthesized at 146 kbar. Note, however, that the pressure required to allow pyroxene solubility in garnet is substantially lower in Fe-rich systems than in Mg- and Ca-rich systems⁶. As the garnets under discussion are reasonably Fe-rich, the pressures required for their synthesis should not be as high as those required to produce pyroxene–garnet solid solution in the natural garnet lherzolite⁶. Therefore, no restricted range of likely depths of origin can be justified on the available evidence. Note that as a group 1 kimberlite¹⁰ the Monastery diatreme has an asthenospheric signature, and the diamonds with group B inclusions are therefore not constrained to a lithospheric origin in the absence of any knowledge of their isotopic characteristics.

De Beers Consolidated Mining and the CSIR provided financial support. H. S. Pienaar of the University of Stellenbosch performed the X-ray diffraction analyses. F. R. Boyd and B. Harte carried out independent microprobe analyses as checks on the data reported. We thank A. P. le Roex, D. R. Bell and S. E. Haggerty for fruitful discussions. We thank GEMEX and the mine manager of Monastery Mine, Mr A. P. Van Jaarsveld, for access to the mine and for arranging the sampling of diamonds. J. Hartley and A. van Niekerk helped to select the diamonds with inclusions.

Forest changes in the Amazon Basin during the last glacial maximum

Kam-biu Liu* & P. A. Colinvaux

Department of Zoology, The Ohio State University,
484 West 12th Avenue, Columbus, Ohio 43210, USA

We report here the discovery of forest beds in the Amazon Basin radiocarbon dated to the Wisconsin–Würm glaciation. These are the first dates from the last glaciation determined on Amazonian samples. The locality is in Ecuador, at 1,100 m elevation, near the upper limit of the present Amazonian rainforest. Both pollen spectra and *Podocarpus* wood in the deposits suggest that vegetation comparable to the present Andean forest grew at least 700 m lower than it does now, suggesting a temperature depression of at least 4.5 °C for the Amazon lowlands.

The forest beds are exposed along road cuts at two sites near Mera (1°28' S, 78°6' W, elevation 1,100 m) in Oriente Province, Ecuador (Fig. 1). The area has a mean annual temperature of 20.8 °C and precipitation of >4,800 mm, making it one of the wettest places in the Amazon Basin¹. The present vegetation is tropical forest of high diversity, at the transition between lower montane rainforest and the true lowland rainforest which begins at ~800 m elevation².

At the first exposure, an organic bed ~2 m thick is overlain by ~12 m of largely inorganic deposit (Fig. 2). Unsorted angular boulders both above and below the organic layer are embedded in a clastic matrix, suggesting lahars, though this must be confirmed by further field work. A darker lithological unit, possibly organic, overlies the upper debris flow and is in turn overlain by a fluvial sequence of clast-supported gravel and sand.

The organic bed has woody twigs or roots up to 10 cm in diameter running through it, has a loss-on-ignition ranging from 30 to 64%, and has high pollen concentrations. It thus appears to be a marsh or soil deposit that accumulated before burial under a debris flow. Two wood samples were collected *in situ* from the forest bed (samples 1 and 5) and sediment samples were collected at 0.3-m intervals for pollen analysis. Wood sample 5 yielded a radiocarbon date of $33,520 \pm 1,010$ yr BP (B-9618).

The second exposure lies about 3 km east of the first. The road-cut section is ~20 m high here and consists of deeply weathered fluvial sand at the base, overlain unconformably by a clast-supported gravel with rounded boulders. The forest bed, ~2 m thick, lies above the gravel and is overlain by fluvial sand. It could not be reached to obtain samples, but slumped blocks containing parts of tree trunks and stumps up to 30 cm in diameter at the foot of the section had apparently fallen from the fossil forest bed. This wood was embedded in a clay-supported matrix of angular pebbles. Wood samples numbers 2–4 were taken from the slumped blocks. Sample 4 has a radiocarbon age of $26,530 \pm 270$ yr BP (B-10170).

Wood samples from both forest beds were submitted to R. B. Miller (USDA Forest Products Laboratory, Madison) for identification. Wood samples 1, 2 and 4 are soft wood from conifers, although poor preservation precludes more precise identification. *Podocarpus* is the only conifer genus now occurring naturally in Ecuador³. *Pinus*, the conifer next nearest to Ecuador, grows no nearer than Nicaragua, at least 1,000 km away⁴. It is therefore reasonable to conclude that wood samples 1, 2 and 4 are of *Podocarpus*. There are indications that sample 1, from the first site, is of a different species from the 6,000-yr younger samples 2 and 4 of the second site.

Wood samples 3 and 5 are of hardwoods, sample 5 possibly of the genus *Tovomitia* (Guttiferae), a genus with both Andean and Amazonian species in the modern flora of Ecuador.

Fig. 1 Regions of Ecuador showing the Mera site of the Pleistocene forest beds and of the suite of surface samples. 1, Lake Conru; 2, Lake San Marcos; 3, Yaguarcocha; 4, Lake Yambo; 5, Rum Tum; 6, Lake Sta. Cecilia; 7, Lake Agrio; 8, Añangucocha; 9, Puyo Bog; 10, Lake Kumpak⁵.

Fig. 2 Mera forest bed: first exposure. Arrows mark edges of polleniferous organic layer containing woody parts of *Podocarpus* dated at $33,520 \pm 1,010$ yr BP.

Pollen concentration (calculated by the exotic pollen technique) of 660,000 grains per cm³ in a sample of the organic bed at site 1 is almost an order of magnitude higher than concentrations typical of the Andean and Amazonian lake samples of Fig. 1. Table 1 compares the percentage pollen spectra from this sample with 10 surface or recent spectra from Ecuador, 5 from the Andes and 5 from the Amazon forest. The sample from Puyo

Sites shown on Fig. 1. Añangucocha sample is from surface pinches of moist forest soil; Puyo Bog is surface organic matter of a tropical swamp; Rum Tum is mud from a small pond and Yaguarcocha is from just below the settlement layer of a sediment core to yield pollen from the Interandean Plateau before human disturbance. Remaining samples are from mud-water interfaces of lakes. We distinguish >200 pollen taxa in Amazonian fossil pollen samples, although many of these cannot yet be given taxonomic names. We have included as 'others' many identifiable, but infrequent pollen types as well as a considerable number of tricolporate and tricolpate taxa yet to be identified. We have also combined subdivisions of other taxa like Moraceae and Urticaceae.

Bog is from within 5 km of site 1 in the same forest type. Table 1 shows that the pollen rain falling at Mera 33,000 yr ago is comparable to pollen of high elevations in the modern Andes and not to pollen emanating from the lowland rainforest like that falling near Mera today. The inclusion of significant percentages of the Andean taxa *Alnus* and *Hedyosmum* is particularly striking, as is the virtual absence of the *Cecropia* found at high percentages in every sample we have yet examined from Holocene and surface samples from Ecuadorian Amazonia, including the immediate vicinity of Puyo.

The Pleistocene pollen assemblage is Andean, although not closely comparable to pollen from any modern facies of the Andean forests. For instance, the taxa Melastomataceae, monolete fern spores, and *Hedyosmum* are in proportions not closely matched by the Andean spectra available. One explanation of an unusual pollen assortment would be pollen transport and redeposition by streams mixing pollen from different elevations, but the very high pollen concentration and organic matrix of the deposit make it unlikely that the beds represent stream deposits. This conclusion is supported by the presence of *Podocarpus* megafossils (twigs or roots) embedded in the polleniferous organic matrix of site 1. The *Podocarpus* megafossils are unlikely to have been redeposited in a richly polleniferous organic sediment by rapid mountain streams. The data thus suggest that Andean forest including *Podocarpus* grew at 1,200 m elevation at times during the last glacial cycle.

Podocarpus typically grows today in the Andean forest between the 2,000- and 3,500-m contours in Ecuador and Colombia^{2,3,5,6}. Four species occur naturally in Ecuador: *P. montanus* (including *P. montanus* var. *densifolius*), *P. oleifolius*, *P. glomeratus* and *P. sprucei*. Altitudinal ranges given in the literature are 2,000–2,800 m for *P. oleifolius*, 2,500–4,000 m for *P. glomeratus* and 2,000–3,000 m for the whole section of *Stachycarpus*^{3,5}. These reports suggest that 2,000 m is about the lowest altitude at which populations of *Podocarpus* are to be expected. The lowest confirmed modern elevation in the records of the Fundacio Natura of Ecuador is 1,800 m.

The late Pleistocene populations of *Podocarpus* grew at least 700 m below the lowest modern populations. If, as seems likely for mountain conifers, the altitudinal ranges are temperature dependent, we can calculate the necessary temperature depression. Assuming a lapse rate of 0.65°C per 100 m, the minimum lowering of mean annual temperature is 4.5°C. As the pollen data suggest extensive montane forests at this eleva-

tion, the actual lower limit of *Podocarpus* was certainly below 1,100 m and the actual temperature depression >4.5°C. This conclusion is compatible with earlier estimates of a temperature depression of 6°C on the altiplano of Colombia⁶. These new data, however, are the first to demonstrate temperature depressions of this magnitude in the Amazon lowlands themselves.

Note that both our radiocarbon dates fall within various definitions of a mid-Wisconsin interstade⁷, suggesting that forest and temperature depressions at full glacial times were even larger than our calculations suggest. There are no data which could establish the extent to which an interstadial was expressed along the American Equator, although an episode of glacial advance younger than 25,000 yr ago has been documented from the Ecuadorian Andes⁸. It is likely that the displacement of vegetation and climate during the glacial maximum at 18 K was even larger than that suggested by the Mera data.

These data are of particular interest in view of the hypothesis that much of the Amazon Basin was arid during times of glacial maxima, with the rainforest reduced to several large refugia in regions of highest modern rainfall^{9–11}. Prominent among suggested refugia is the region between the Napo and Pastaza rivers in which the Mera sites lie, since this is the Amazonian region of highest contemporary rainfall. Our pollen data show that at least part of the territory of this supposed refugium in fact supported forest comparable to modern, montane Andean forest from 33,000–26,000 yr BP in Wisconsin–Würm times.

The research was supported by NSF grants to The Ohio State University. We thank M. Steinitz-Kannan, R. B. Miller, R. Kesel, K. N. Olson, I. Frost, M. Miller, M. Scheutzw, T. Steinitz, H. Steinitz, M. Moreno Espinosa and many people of Ecuador who helped, and made us welcome.

Calcium gradients in single smooth muscle cells revealed by the digital imaging microscope using Fura-2

David A. Williams, Kevin E. Fogarty, Roger Y. Tsien* & Fredric S. Fay

Department of Physiology, University of Massachusetts Medical School, 55 Lake Avenue, Massachusetts 01605, USA

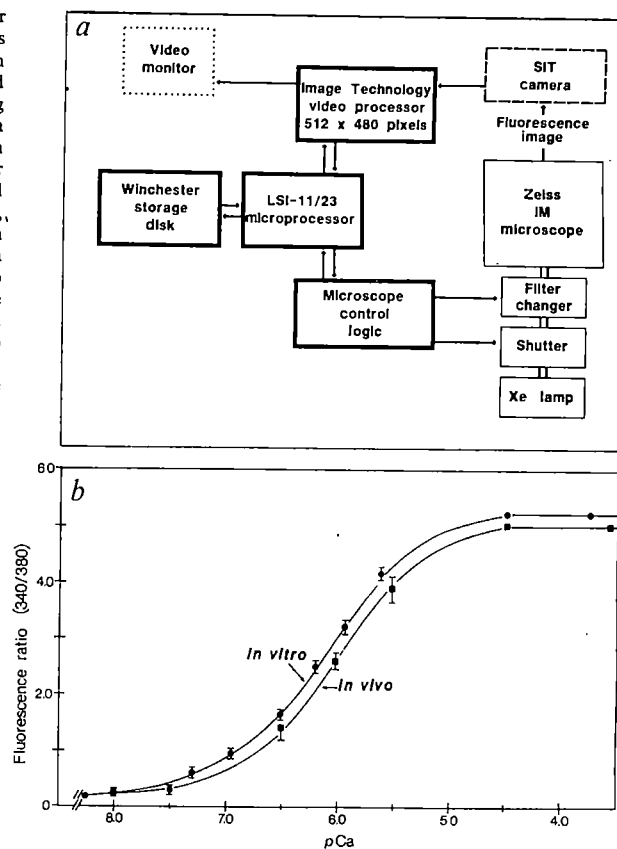

*Departments of Physiology & Anatomy, University of California, Berkeley, California 94720, USA

Calcium is believed to control a variety of cellular processes, often with a high degree of spatial and temporal precision. For a cell to use Ca^{2+} in this manner, mechanisms must exist for controlling the ion in a localized fashion. We have now gained insight into such mechanisms from studies which measured Ca^{2+} in single living cells with high resolution using a digital imaging microscope and the highly fluorescent Ca^{2+} -sensitive dye, Fura-2. Levels of Ca^{2+} in the cytoplasm, nucleus and sarcoplasmic reticulum (SR) are clearly different. Free $[\text{Ca}^{2+}]$ in the nucleus and SR was greater than in the cytoplasm and these gradients were abolished by Ca^{2+} ionophores. When external Ca^{2+} was raised above normal in the absence of ionophores, free cytoplasmic Ca^{2+} increased but nuclear Ca^{2+} did not. Thus, nuclear $[\text{Ca}^{2+}]$ appears to be regulated independently of cytoplasmic $[\text{Ca}^{2+}]$ by gating mechanisms in the nuclear envelope. The observed regulation of intranuclear Ca^{2+} in these

contractile cells may thus be seen as a way to prevent fluctuation in Ca^{2+} -linked nuclear processes during the rise in cytoplasmic $[\text{Ca}^{2+}]$ which triggers contraction. The approach described here offers the opportunity of following changes in Ca^{2+} in cellular compartments in response to a wide range of stimuli, allowing new insights into the role of local changes in Ca^{2+} in the regulation of cell function.

The resting Ca^{2+} distribution in smooth muscle was determined using a digital imaging microscope to measure the fluorescence of enzymatically disaggregated toad (*Bufo marinus*) stomach cells¹ loaded with Fura-2². This cell type has been studied in detail (for review see ref. 3), previous work having revealed that, like other types of smooth muscle, these cells use Ca^{2+} from different sources for different stimuli⁴⁻⁶. The recording system (shown schematically in Fig. 1a) was developed to detect light within a single cell with extremely high accuracy, sensitivity and resolution, so that a very small number of molecules could be detected in a limited region of a cell⁷. $[\text{Ca}^{2+}]$ at each point in a cell was determined by measuring the fluorescence intensity (500 nm, emission) with excitation at 340 nm and at 380 nm² (Fig. 2a, b). The 340-nm image (Fig. 2a) showed large regional inhomogeneities in fluorescence intensity which reflected both Ca^{2+} and dye distribution, and which were also influenced by cell geometry. Division of this image, on a pixel-by-pixel basis, by that obtained with 380 nm (Fig. 2b) resulted in a ratio image (Fig. 2c) in which variations in fluorescence intensity within the cell were indicative² of spatial variation in $[\text{Ca}^{2+}]$. The nuclear and sub-plasmalemmal fluorescence detail,

Fig. 1 Acquisition of Fura-2 cellular fluorescence images and determination of cellular $[\text{Ca}^{2+}]$. **a**, Schematic illustration of digital imaging microscope used to acquire and process images of cellular Fura-2 fluorescence. Fluorescence of Fura-2-loaded single smooth muscle cells was imaged using a Zeiss Ultrafluor 100 \times , NA = 1.25 objective and an inverted microscope (Zeiss IM) equipped for epifluorescence. Video images were obtained using a silicon-intensified target camera (Dage MTI, model 66), with the output digitized to a resolution of 512 \times 480 pixels by an Image Technology video analyser with each point in the image being assigned a value from 0 to 255 depending on intensity. The shutter/filter changer were obtained from Digital Microscope Accessories Co. The optics and digital imaging system provide better than 0.25 μm resolution in a given image plane. However, the large depth of focus of the fluorescent microscope results in information from a much greater depth than this being present in a given image plane⁷. For example, light from a point source 2 μm either above or below a given specimen plane will be attenuated to only 30% at the position in the image corresponding to the point source. Images were stored on a high-capacity Winchester disk (20 megabyte capacity) and digitally analysed using a PDP-11/23 microcomputer. Multiple video frames were sequentially added to memory to increase the signal-to-noise ratio in the averaged image. To correct for spatial variations in dark current of the camera, averaged images, obtained without input to the camera, were subtracted from the images on a pixel-by-pixel basis. To correct for spatial variations in the intensity of the excitation source, as well as spatial variations in camera gain, the image was multiplied pixel-by-pixel with a 'system gain normalization' map. This map was constructed by obtaining an image of a uniform fluorescent field (a well-mixed solution of Fura-2 free acid), with intensities at each point being divided by the mean fluorescence intensity so that the gain normalization did not change the mean grey level of an image. Images of Fura-2 fluorescence at 500 nm emission were obtained with 340 and 380 nm excitation wavelengths using filters from Dittic Optics Inc. (Hudson, Massachusetts) (emission filter, 500 nm, Halfwidth, 20 nm; excitation filters, 340 nm, Halfwidth, 10 nm; 380 nm, Halfwidth, 10 nm). The ratio image ($R_{340/380}$) was achieved from the division of the 340-nm image by the 380 nm image on a pixel-per-pixel basis. A fluorescence intensity threshold was set before the division to exclude non-cellular regions from the determination of the ratio image. We have not attempted to interpret information in pixels immediately adjacent to the cell edge due to a low signal-to-noise ratio, and the extreme sensitivity of the ratio image at these points to small mechanical and/or electronic shift between the two images. All images were photographed using a Celtic Technology video/filter recorder. **b**, Relationship between Fura-2 fluorescence ratio and $[\text{Ca}^{2+}]$. *In vitro* calibration: smooth muscle cells were loaded with Fura-2 (Fura-2/AM) for 90 min. The external loading solution (amphibian Krebs Ringer or a similar HEPES-based buffer) was removed by gentle centrifugation (~ 200 r.p.m.) and replaced by a solution very like the composition of the intercellular milieu: (mM) K^+ , 100; Na^+ , 30; Mg^{2+} , 1; ATP, 5; Balanced Electrolyte Solution, 20. Small aliquots of cells (300 μl) were each exposed to different external $[\text{Ca}^{2+}]$. The $p\text{Ca}$ of the bathing solution was controlled by varying the ratio of Ca-EGTA/EGTA, and was determined by potentiometric titration of free and total (~ 10 mM) EGTA concentrations by CaCl_2 and CdSO_4 , respectively^{25,26}. This solution also contained 1–2 μM ionomycin to allow equilibration of intra- and extracellular Ca (ref. 6). Higher concentrations of ionomycin (3–5 μM) can completely remove the external cell membrane in this cell type. Fluorescence ratios (340/380) were obtained from several individual cells from each aliquot. Absolute measured ratios are displayed as a function of the calculated $p\text{Ca}$ of the external solution. $[\text{Ca}^{2+}]$ determined using this calibration curve coincided closely ($\pm 5\%$) with values determined using the standard calibration equation (Fig. 3 legend). Possible differences in dye properties due to binding to highly immobile cellular sites were investigated by determining the fluorescence emission anisotropy ($r = (I_{\parallel} - I_{\perp}) / (I_{\parallel} + 2I_{\perp})$)²⁷ under the microscope (380 nm excitation). Fluorescence anisotropy values within different cellular compartments (cytoplasm, 0.08 ± 0.01 , $n = 11$; nucleus, 0.08 ± 0.02 , $n = 6$) were not significantly different from those produced by free dye in solution (0.05 ± 0.01 , $n = 8$). Much higher anisotropies (up to 0.34) are observed when the dye is embedded in highly viscous solutions in cuvettes. *In vitro* calibration: Fura-2 pentapotassium salt (50 μM) was added to small volumes of buffer (mM): K-MOPS, 10; 100; Mg^{2+} , 1; $\text{K}_2\text{H}_2\text{-EGTA} + \text{Ca-EGTA}$ 10; pH 7.20) and sealed in Lucite wells. Each volume contained a different $[\text{Ca}^{2+}]$ attained and measured as described above. Ratios were determined under the digital imaging microscope from fluorescence intensities at 340 and 380 nm excitation corrected for the background fluorescence obtained in the absence of Fura-2.

evident particularly in the 340 nm image, was still present in the ratio image, indicating that it reflects localized areas of higher $[Ca^{2+}]$, rather than simple differences in dye concentration.

The precise relationship between the fluorescence ratio (340/380) and free $[Ca^{2+}]$ in the intracellular environment was determined by exposing cells to solutions of varying $[Ca^{2+}]$ in the presence of levels of Ca^{2+} -ionophore previously shown⁶ to result in equilibration of intracellular and extracellular $[Ca^{2+}]$. We found that the fluorescence ratio varied in response to changes in cellular $[Ca^{2+}]$ in a manner virtually identical to that of free dye in solution (Fig. 1b). The *in situ* calibration curve was used in turn to calculate $[Ca^{2+}]$ at each point within the cell (as described in Fig. 3). Figure 3a shows the resulting map of spatial variations of $[Ca^{2+}]$ within this cell. Intracellular variations in $[Ca^{2+}]$ are displayed as a solid surface whose height at each pixel is proportional to pCa . This image shows quite strikingly that Ca^{2+} is not uniformly distributed within the smooth muscle cell, but is present at higher concentrations inside the nucleus than in the cytoplasm. It is also present at higher concentrations in sub-sarcolemmal sites whose distribution is remarkably similar to what has been presumed to be SR in other smooth muscles⁸. Further support for the assumption that these regions reflect $[Ca^{2+}]$ inside the SR comes from observations of Fura-2 fluorescence in skinned smooth muscle cells. In saponin-skinned cells, where the SR is intact, areas of high $[Ca^{2+}]$ along the cell margins were apparent, whereas in cells skinned with Triton X-100, which permeabilizes both sarcolemma and SR, these areas were no longer detectable (G. J. Kargacin, D.A.W. and F.S.F., unpublished observations). Mean $[Ca^{2+}]$ over any region in these cellular maps was calculated using interactive graphics software to define the boundaries of the selected regions. Cytoplasmic $[Ca^{2+}]$ in 45 cells was 137 ± 13 (s.e.m.) nM, which compares favourably with other determinations made in the same cell type using other techniques (129 ± 4 nM ($n=22$), as measured from quin2 fluorescence in cell suspensions⁶ and 163 (148 with Na^+ correction) ± 20 nM ($n=16$) using a Ca -sensitive microelectrode; H. Yamaguchi, per-

sonal communication). Nuclear $[Ca^{2+}]$ in resting smooth muscle cells was significantly higher than cytoplasmic, averaging 245 ± 20 nM in 13 cells and being 220 nM in the cell shown in Figs 2 and 3a. Note that when $[Ca^{2+}]$ is calculated from measurements of total cell fluorescence (for example, as in fluorometric measurements using cells in suspension), fluorescence contributions from the nucleus and SR would result in an overestimate of cytoplasmic $[Ca^{2+}]$ by 8–10%. This source of contamination can be significantly reduced by using shorter dye loading times to reduce dye entry into the SR (see also Fig. 2 legend).

The observation that free $[Ca^{2+}]$ within the cell nucleus appears to be higher than in the cytoplasm is an unexpected finding which might be explained if intranuclear $[Ca^{2+}]$ were regulated by nuclear membrane-dependent processes, or may represent an artefact resulting from modified behaviour of the dye in the nuclear environment. This latter explanation seems unlikely in the light of several findings. One finding is that the dye inside the nucleus has the same rotational freedom (as measured by fluorescence emission anisotropy) as that in the cytoplasm, suggesting that the dye is not bound to highly immobile intracellular sites (see Fig. 1b). An even more direct test of this possibility was obtained in experiments where cells were exposed to the Ca^{2+} -selective ionophore ionomycin, which resulted in collapse of the $[Ca^{2+}]$ gradient between nucleus and cytoplasm, as well as between SR and cytoplasm (see Fig. 3b). This was also seen in ionomycin-treated cells in which cytoplasmic $[Ca^{2+}]$ was maintained below normal by incubation of cells in external $[Ca^{2+}]$ levels below 1.8 mM. The maps derived from the fluorescence ratio (340/380) revealed no differences between nucleus, SR and cytoplasm, although the higher dye content of the nucleus was still clearly evident in non-ratio images (not shown). Finally, while not all cells so far studied in this manner (human neutrophils, mouse lymphocytes, BALB/c 3T3 cells) exhibit a higher $[Ca^{2+}]$ in the nucleus than in the cytoplasm, all these cells did exhibit different intranuclear $[Ca^{2+}]$ from that of the cytoplasm, suggesting that Ca^{2+} regulation at the nuclear-cytoplasmic interface may be a general cellular property.

Fig. 2 Images of Fura-2 fluorescence in a single smooth muscle cell. *a*, 340 nm excitation, 500 nm emission; *b*, 380 nm excitation, 500 nm emission; *c*, ratio 340/380 image. Cell length, 150 μ m; maximum cell diameter, 11 μ m. All images were obtained as described in Fig. 1a legend. The fluorescence image displayed in *a* indicates a large degree of intracellular heterogeneity in fluorescence intensity, reflecting regional differences in dye and Ca^{2+} concentration and also that the dye can enter subsarcolemmal sites (SR). The ratio image (*c*) indicates that the cellular ionized $[Ca^{2+}]$ is apparently higher in the SR and nucleus. To determine if the high $[Ca^{2+}]$ measured over the nucleus merely reflects high $[Ca^{2+}]$ within the perinuclear space projected, because of the large depth of focus of the fluorescence microscope, onto the profile of the nucleus, we digitally calculated the image to be expected for this possibility. We assumed that intranuclear and cytoplasmic $[Ca^{2+}]$ were equal and that the perinuclear space was 0.2 μ m wide, containing a 10-fold higher $[Ca^{2+}]$. Nuclear dimensions were those determined from the cell displayed in *a–c*. The expected image was determined by convolving this model cell with the point spread function of the optical system which was determined as described previously⁷. A profile of $[Ca^{2+}]$, determined midway through the nucleus of the resultant image (results not shown), differed considerably from that observed in the actual image in that $[Ca^{2+}]$ in this image was higher along the periphery of the nucleus than over its centre. Just the opposite pattern was actually observed. A similar procedure was used to assess the contribution of SR and nuclear fluorescence to $[Ca^{2+}]$ measured in the cytoplasm. The cell was modelled as a cylinder, 150 μ m long with SR distributed in an outer annulus 1 μ m wide, encircling a cylinder of cytoplasm 10 μ m diameter. The nucleus (2 μ m wide, 10 μ m long) occupied a central position. Fluorescence intensities in each model area were calculated from the mean values in Fig. 2 at each wavelength. This model was convolved with the point spread function of the microscope. In the mid-focal plane of the model, at points adjacent to and significantly away from the nucleus, calculations revealed that the $[Ca^{2+}]$ would be overestimated by $\sim 15\%$ and 3% in these two locations, respectively, due to contribution of out-of-focus information from non-cytoplasmic sites.

Methods. Fura-2⁸ was introduced into these cells by incubating small aliquots (300 μ l) of cells in amphibian physiological saline (APS) at 30 $^{\circ}$ C with 0.3 μ M Fura-2/AM (the acetoxymethyl ester form of the dye). After 60–90 min of incubation, cellular esterases had cleaved and entrapped 20–100 μ M of the working form of the dye (as determined fluorometrically in cell suspensions), suitable concentration for monitoring most physiological processes under investigation. Substantial dye loading into the SR could be achieved by simply increasing the duration of the loading phase to ~ 180 min and is probably enhanced by the peripheral location of the SR in this cell type. The images displayed here and in Fig. 3 were all obtained after loading for 180 min (cytosolic Fura-2 concentration 150–160 μ M). Dye which had been loaded and cleaved by smooth muscle cells displayed spectral properties characteristic of free dye (acid) in solution².

Fig. 3 Maps of the spatial variation in $[Ca^{2+}]$ in smooth muscle cells. Profiles of pCa in a relaxed smooth muscle cell (*a*, from Fig. 2c) and an ionomycin-treated cell in the presence of normal (1.8 mM) extracellular calcium (*b*). Vertical heights at each pixel in these images are proportional to the pCa at that location within the cell. The areas of high intensity evident in the ratio image (Fig. 2c), the nucleus and subsarcolemmal sites, (presumably the SR), are clearly apparent in *a*. Average $[Ca^{2+}]$ in each of these cell areas are: cytoplasm, 130 nM; nucleus, 220 nM; SR, 500 nM. The $[Ca^{2+}]$ gradients between the cytoplasm, nucleus and SR are no longer evident in ionomycin-treated cells.

Methods. Fluorescence ratio images were converted to $[Ca^{2+}]$ using the equation $K_D[(R - R_{min})/(R_{max} - R)]\beta = [Ca^{2+}]$,

where R is the measured 340/380 ratio at each point in the cell, R_{max} and R_{min} are the fluorescent ratios of the same point in the cell, for a well-mixed solution of Fura-2 + Ca^{2+} and Fura-2, respectively, and β is the ratio of fluorescence at 380 nm excitation for Fura-2/Fura-2 + Ca^{2+} . The K_D of the intracellular dye was determined from the data in Fig. 1b to be 200 nM. Note that the $[Ca^{2+}]$ calculated by determining the ratio on a point-by-point basis (as above) is not equivalent to that determined by taking the ratio of the average fluorescence of large areas within the cell as the latter method would tend to underestimate the real mean $[Ca^{2+}]$ because of the non-distributive aspect of the calculation as well as the nonlinear relation between the 340/380 fluorescence ratio and $[Ca^{2+}]$. $[Ca^{2+}]$ values were converted to pCa and displayed as a solid surface on a Lexidata Model 3400 Imageview/Solidview Graphics System. These images were constructed using a standard surface modelling system which represented the cell surface as a group (160,000) of triangular polygons. Random high-frequency noise was removed by filtering (or convolving) the image with a gaussian filter whose width at half-height was 3 pixels.

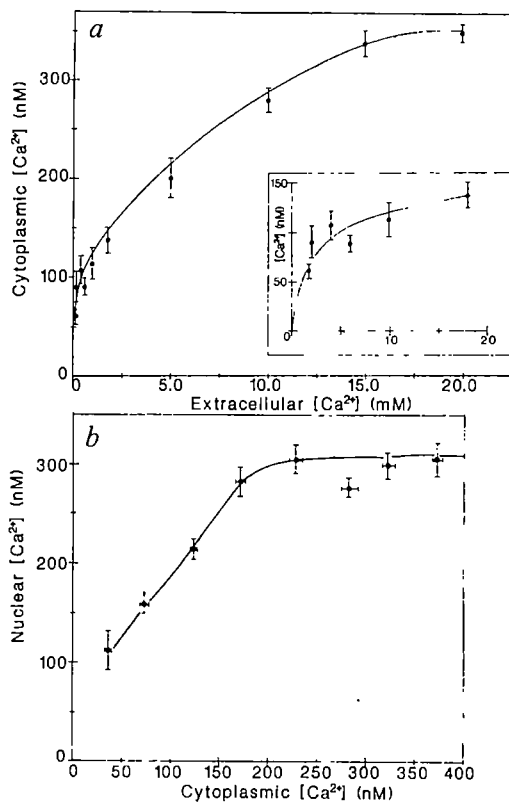

Fig. 4 Dependence of cytoplasmic and nuclear $[Ca^{2+}]$ on extracellular and cytoplasmic $[Ca^{2+}]$, respectively. *a*, Cytoplasmic $[Ca^{2+}]$ was determined in randomly selected areas of multiple smooth muscle cells as a function of external $[Ca^{2+}]$. Results are expressed as mean \pm s.e.m. with a minimum of 10 observations for each point. The inset shows, on an expanded scale, the relationship between cytoplasmic $[Ca^{2+}]$ and extracellular $[Ca^{2+}]$ below 2.0 mM. As can be seen, cytoplasmic $[Ca^{2+}]$ was relatively constant in the face of a large change in the transmembrane $[Ca^{2+}]$. The relative constancy of cytoplasmic $[Ca^{2+}]$ might reflect saturation of carrier-mediated Ca^{2+} influx, or the operation of a pumping mechanism with a high Hill coefficient (>2.8). This Hill coefficient is inferred from the observed dependence of cytoplasmic $[Ca^{2+}]$ on extracellular $[Ca^{2+}]$, assuming that Ca^{2+} permeability is fixed and that influx increases 36-fold at 0.5–18 mM extracellular $[Ca^{2+}]$ which, in the steady state, must be accompanied by a similar increase in Ca^{2+} pumping out of the cell. This requires that over the observed range of cytoplasmic $[Ca^{2+}]$ (130–350 nM), the Hill coefficient for Ca^{2+} pumping is 2.86, a high level of positive cooperativity. *b*, Dependence of nuclear $[Ca^{2+}]$ on cytoplasmic $[Ca^{2+}]$. The cytoplasmic $[Ca^{2+}]$ values determined in *a* were placed into 50-nM groupings (0–49, 50–99 ... 350–399) irrespective of the extracellular $[Ca^{2+}]$ which produced each cytoplasmic $[Ca^{2+}]$. These values were then averaged and the respective nuclear $[Ca^{2+}]$ values plotted as a function of average $[Ca^{2+}]$ for each cytoplasmic $[Ca^{2+}]$ range. All results are presented as means \pm s.e.m. Lines were fitted to the data points by eye.

The observation of a $[Ca^{2+}]$ gradient between both cytoplasm and extracellular space as well as between nucleus and cytoplasm suggests that both the plasma membrane and nuclear membrane have important Ca^{2+} -regulatory functions. To obtain further insights into the existence and nature of these processes, we exposed smooth muscle cells to solutions of varying extracellular $[Ca^{2+}]$ and determined the steady-state distribution of Ca^{2+} across the sarcolemma and nuclear membrane (Fig. 4). A strong dependence of cytoplasmic $[Ca^{2+}]$ on extracellular $[Ca^{2+}]$ was seen only below 0.5 mM (Fig. 4). By contrast, cytoplasmic $[Ca^{2+}]$ changed by no more than 3-fold as $[Ca^{2+}]_{out}$ was varied over a 36-fold range from 0.5 to 18 mM. This may be indicative of the involvement of a saturable carrier protein mediating Ca^{2+} influx in the plasmalemma or an outwardly directed Ca^{2+} pump having a large Hill coefficient (~ 3) between 130 and 350 nM $[Ca^{2+}]$ (see Fig. 4 legend). The existence of an inverse relation between Ca^{2+} 'permeability' and extracellular concentration has in fact been demonstrated previously for these cells⁶.

The changes in cytoplasmic $[Ca^{2+}]$ induced by varying extracellular $[Ca^{2+}]$ allowed us to observe the dependence of intranuclear $[Ca^{2+}]$ on cytoplasmic $[Ca^{2+}]$. As can be seen in Fig. 4b, although nuclear $[Ca^{2+}]$ closely followed changes in cytoplasmic $[Ca^{2+}]$ below the resting level (130 nM), it was virtually unaffected by increases in cytoplasmic $[Ca^{2+}]$ above this value, thereby revealing for the first time membrane-dependent mechanisms for regulating intranuclear $[Ca^{2+}]$. We doubt that higher intranuclear $[Ca^{2+}]$ is the simple result of a Donnan effect of excess negative charge in the nucleus relative to the cytoplasm. Ionomycin should not directly affect a Donnan gradient yet does abolish the observed nuclear-cytoplasmic difference. Furthermore, a Donnan effect would predict a constant nuclear to cytoplasmic free $[Ca^{2+}]$, in contradiction to the results shown in Fig. 4b, and should also influence the distribution of all permeant ions between nucleus and cytoplasm; however, studies of monovalent ion distribution by others^{9,10} indicate that any Donnan effect must be quite small. Finally, a Donnan potential that accumulates Ca^{2+} would repel Fura-2 and its Ca^{2+} complex (-5 and -3 charged, respectively), whereas the dye concentration is actually higher in the nucleus. The possibility that the nuclear membrane acts to regulate nuclear $[Ca^{2+}]$ may initially seem surprising given ultrastructural data revealing the existence of pores in this membrane¹¹, observations that dyes of relative molecular mass $<20,000$ rapidly enter the nucleus when injected into cells¹², and measurements of monovalent ion distribution between nucleus and cytoplasm revealing equivalent concentrations^{9,10}. On the other hand, there are data to support the proposal that the nuclear membranes regulate $[Ca^{2+}]$. First, the nuclear pores are not patent but filled

with electron-dense material arranged in an ordered manner¹¹. Second, transport functions are known to reside in the nuclear membranes—a system for active uptake of specific proteins has been extensively studied^{13–15} and, particularly germane to the present proposal, a Ca^{2+} -ATPase has been reported to exist in nuclear membranes^{16,17}. Finally, measurement of total Ca^{2+} with the electron microprobe, while not directly comparable to the present data on free Ca^{2+} , suggest that nuclear Ca^{2+} is somehow screened from the effect of increased cytoplasmic Ca^{2+} during contraction of rabbit portal-anterior mesenteric vein¹⁸, although screening is not apparent in the rabbit main pulmonary artery¹⁹.

The proposal that nuclear function may be subject to Ca^{2+} -linked regulation, as are many cytoplasmic processes, is certainly supported by recent observations revealing the presence of the Ca^{2+} -linked modulatory protein, calmodulin, within the nucleus of various cells²⁰, as well as *in vitro* observations revealing a Ca^{2+} or calmodulin sensitivity, for several known intranuclear

enzymes^{21–23} and for prolactin gene expression²⁴. It remains to be seen which nuclear processes are indeed regulated by Ca^{2+} *in situ* and if and when during cell activity nuclear $[\text{Ca}^{2+}]$ changes. The demonstrated ability to measure $[\text{Ca}^{2+}]$ with a high degree of spatial resolution in single living cells opens the exciting possibility of measuring changes in $[\text{Ca}^{2+}]$ in various cellular compartments (for example, cytoplasm, nucleus and SR) during changes in physiological activity to explore such questions.

We thank Dr D. E. Wolf for his assistance and advice with fluorometric techniques, Ms L. J. Harris for technical expertise, Ms S. A. Borsuk for clerical assistance and Mr Cyril Rodgers for help in the design and fabrication of components of the digital imaging microscope. This manuscript benefited from the critical reading of Dr J. L. Conklin. D.A.W. is an Overseas Research Fellow of the National Heart Foundation of Australia. The work was supported by NIH grant HL14523 and by a grant from the Muscular Dystrophy Association.

Sequences homologous to the P mobile element of *Drosophila melanogaster* are widely distributed in the subgenus *Sophophora*

Robert A. Lansman, Simon N. Stacey,

The biological properties of the P element of *Drosophila melanogaster* differ from those of other mobile elements in this genus in that its mobility is associated with dysgenic traits that might be expected to limit its distribution or spread¹. The P element is widely distributed among natural populations of *D. melanogaster*, but is absent from strains that have been maintained in the laboratory for more than thirty years². This observation prompted speculation that the P element has recently invaded and spread horizontally through *D. melanogaster*^{3,4}, a hypothesis supported by the observation that P elements are absent from the *D. melanogaster* sibling species⁵. However, sequences homologous to P elements have been found recently in *Drosophila paulistorum*, a quite distant relative⁶. This finding undermines any simple hypothesis about the origin of P elements, and demands a thorough analysis of the distribution and conservation of the P element within the subgenus *Sophophora*. We show here that the P element is present in every species group in the subgenus *Sophophora*, but that its distribution within species groups can be discontinuous. The P homologues from different species are not identical; furthermore, their genomic localization differs from that found in *D. melanogaster*.

D. melanogaster belongs to the subgenus *Sophophora*. This subgenus has 145 species distributed among four species groups: *melanogaster*, *obscura*, *saltans* and *willistoni*⁷. We examined 20 species from the subgenus, representing all 4 species groups.

The species chosen differ in their geographical range, habitat and relatedness. The divergence of the *melanogaster* group from both the *willistoni* and *obscura* species groups is estimated to have occurred about 50 million years ago⁸. Table 1 shows the phylogenetic relationships of the species used in this study. About 100 adult flies of each species were examined carefully under a dissecting microscope to confirm their identity, and DNA was prepared from them⁹, digested with *Pvu*II, separated by electrophoresis and transferred to nitrocellulose filters¹⁰. An internal 840-base-pair (bp) *Hind*III fragment from the *D. melanogaster* P element p π 25.1 was purified, labelled and hybridized to the filters (see Fig. 1). The distribution of P homologues within the subgenus under low-stringency wash conditions is shown in Table 1 (see Fig. 1 legend for details). All members tested of the *willistoni* and *obscura* groups have P-element homologues, whereas some species from the *melanogaster* and *saltans* species groups lack sequences with detectable homology to the P element. Previous investigators did not detect P homologues in *D. pseudoobscura*⁵, but this may be due to differences in the hybridization and wash conditions, or to intraspecies differences.

The filters were washed subsequently at increasing stringencies to estimate the degree of similarity between P homologues from the different species and the *D. melanogaster* P element. The representative data shown in Fig. 1 demonstrate that each species group has P-homologous sequences with distinct properties. P homologues from *melanogaster* species are weakly detectable only at low stringency (Fig. 1). More closely related P homologues are found in the *obscura* group species. The hybridization signal is detectable after low- and medium-stringency washes, but is undetectable after high-stringency washes. The most similar P homologues are found in the *willistoni* and *saltans* species groups, in which the signal is retained even when the filters are washed in $0.2 \times \text{SSC}$ at 63°C . Note that all *willistoni* species group members have a 0.9-kilobase (kb) *Pvu*II fragment that co-migrates with the 0.9-kb *Pvu*II fragment from the complete P element of *D. melanogaster*, whereas no member of the *saltans* group has such a fragment. This suggests that the P-homologous sequences differ between the *willistoni* and *saltans*

Fig. 1 Autoradiographs of Southern blots containing Sophophoran species DNA probed with P element DNA from *D. melanogaster*. DNA was prepared from adult flies using slight modifications of a published procedure⁹, digested with *Pvu*II, subjected to electrophoresis on 0.6% agarose gels and transferred to nitrocellulose¹⁰. The 840-bp internal 5' *Hind*III fragment of p π 25.1 was eluted from agarose gels, nick-translated¹⁵ to a specific activity of 0.5–1.0 \times 10⁸ d.p.m. μ g⁻¹ with ³²P-dCTP, and used as a probe. Hybridization conditions were 6 \times SSC, 50% formamide, 5 \times Denhardt's solution¹⁶, 10 mM EDTA, 0.5% SDS for 12–16 h at 37 °C. The filters were washed three times for 15 min each under the following conditions: low stringency (2 \times SSC, 0.1% SDS; room temperature); medium stringency (0.2 \times SSC, 0.1% SDS; 53 °C); high stringency (0.2 \times SSC, 0.1% SDS; 63 °C). The stringency used is indicated below each lane, using the following abbreviations: L (low) and H (high). The species groups and species are indicated above each gel lane. Abbreviations are as follows: mela (*D. melanogaster*), kikk (*D. kikkawai*), eugr (*D. eugracilis*), affi (*D. affinis*), pseu (*D. pseudoobscura*), aust (*D. australosaltans*), neoc (*D. neocordata*), will (*D. willistoni*) and nebu (*D. nebulosa*). The arrowhead indicates the position of a 0.9-kb *Pvu*II fragment which co-migrates with the internal 0.9-kb *Pvu*II fragment of p π 25.1.

groups. The most striking observation is that the P homologues from species more closely related to *D. melanogaster* show least homology to the *D. melanogaster* P elements. Representative P homologues have been cloned from *D. willistoni* and *D. nebulosa*, and have restriction maps very similar to the map of the P element of *D. melanogaster*. A 2.9-kb P homologue from *D. nebulosa* shows extensive DNA sequence conservation compared with p π 25.1 (R.A.L. *et al.*, manuscript in preparation).

The apparent differences among P homologues prompted us to examine the location of these sequences within their respective genomes by *in situ* hybridization. In *D. melanogaster*, the P element can insert at many positions within the euchromatic portion of the genome, and although it can insert into heterochromatin, it is rarely found there^{11,12}. Figure 2 shows the results of *in situ* hybridization using either *D. melanogaster* internal P-element restriction fragments, or using P-homologue sequences cloned from *D. saltans* or *D. nebulosa*. In each of *D. nebulosa*, *D. saltans* and *D. willistoni*, the probe hybridizes extensively to centromeric heterochromatin. Only in *D. willistoni* did we regularly detect at least two euchromatic sites of hybridization. This pattern contrasts with the predominantly euchromatic location of P elements in *D. melanogaster*.

The observation that P homologues are detectable in all species groups of the Sophophoran subgenus might lead one to conclude that the P element is evolutionarily ancient, and that it appeared before the Sophophoran radiation. However, discontinuous distribution of the P homologues within species groups suggests that P elements have invaded some species after the Sophophoran radiation. If the element existed prior to the Sophophoran radiation, then the discontinuous distribution must result from the loss of the P element from some populations, but the observation that P homologues from species most closely related to *D. melanogaster* are the least conserved relative to the *D. melanogaster* P element strongly argues against a single ancient origin of the P element. The fact that P homologues are widespread but not identical in the Sophophoran subgenus suggests that Drosophilids have been subject to multiple invasions at undetermined times from an unknown external source, or alternatively, that P elements occasionally move horizontally from within the genus. The latter suggestion implies that species bearing P homologues should now have, or have had in the past, overlapping ranges. This prediction is supported by the observation that P homologues are present in species

Table 1 Phylogenetic relationships among Sophophoran species used, and distribution of P homologues

Subgenus	Species group	Subgroup	Species	P homologues
Sophophora	melanogaster	ananassae	ananassae	—

		elliptica	emarginata	—
		cordata	neocordata	—

The table shows the species group, subgroup and species of each species used in this study, taken from Throckmorton⁷. All stocks were obtained from the National *Drosophila* Species Resource Center, Bowling Green State University, Ohio. The right-hand column shows whether P homologues were detected under our low-stringency wash conditions (see Fig. 1 legend).

Fig. 2 *In situ* hybridization of P elements to chromosomes of *Sophophora* species. DNA was labelled to a specific activity of $3\text{--}5 \times 10^7$ d.p.m. μg^{-1} with ^{35}S -dCTP and hybridized to polytene chromosomes¹⁷. Hybridization conditions were $5 \times \text{SSPE}$, 50% formamide, $2 \times$ Denhardt's solution¹⁶, $100 \mu\text{g ml}^{-1}$ sonicated salmon sperm DNA, at 35°C for 12–16 h. Slides were washed three times for half an hour each in $2 \times \text{SSC}$ at 50°C , dried through ethanol and prepared for autoradiography¹⁸. **a**, The complete P element p $\pi 25.1$ hybridized to *D. melanogaster*, showing exclusively euchromatic localization of the P elements. **b**, P homologue from *D. nebulosa* subcloned into pUC12, hybridized to chromosomes from *D. nebulosa*, showing chromocentric localization of P elements. **c**, A gel-purified internal fragment from the 3' end of the same *D. nebulosa* homologue used in **b**, hybridized to *D. nebulosa* chromosomes to demonstrate that flanking sequences do not account for hybridization to the chromocentre. **d**, A P-homologous sequence from *D. saltans* hybridized to chromosomes of *D. saltans*. Most grains are observed over the chromocentre. Similar results were obtained when the *D. nebulosa* internal P-element probe was hybridized to chromosomes from *D. saltans* (data not shown). **e**, Hybridization of 3' internal P-element restriction fragment from *D. nebulosa* to chromosomes of *D. willistoni*. Most hybridization is to the chromocentre, although two euchromatic sites can occasionally be detected. **f**, Hybridization of the 840-bp internal 5' *Hind*III fragment from p $\pi 25.1$ used for the genomic Southern analysis hybridized to chromosomes of *D. willistoni*. Two euchromatic sites of hybridization are detected and shown here, although a third site is visible after longer exposure.

whose ranges overlap the South American and Central American range of the *willistoni* species group¹³, like the *saltans* and *obscura* groups⁷, or the nearly cosmopolitan *D. melanogaster* and *Drosophila kikkawai*⁷. The absence of P elements from some species in our sample could have several origins. First, the P element or its as yet unidentified putative vector, could have a limited host range. Second, if the source of the P element is outside the genus *Drosophila*, the source may be limited in its geographical range, perhaps constrained by its primary host. Third, the populations sampled may simply be M strains, whereas other populations of the same species may contain P homologues.

The P homologues from all three species examined by *in situ* hybridization appear to be largely confined to the heterochromatin. This heterochromatic localization may arise because heterochromatin contains a hotspot for integration of P elements in these species. If P factors are not transcriptionally active because they are confined to heterochromatin, then it would not be expected that they would spread through the population. It is interesting that in reactive strains of the IR dysgenic system of *D. melanogaster*, I elements are confined to heterochromatic regions, where presumably they are non-functional¹⁴. Molecular and biological tests of P-homologue function will be required in order to understand the origin and evolution of P elements.

We thank G. M. Rubin for the *D. melanogaster* P element p $\pi 25.1$. We also thank Richard Wennberg for providing the *in situ* result shown in Fig. 2a. This research was supported by a Natural Sciences and Engineering Research Council Strategic grant G1119. S.N.S. acknowledges the support of a Natural Science and Engineering Research Council Postgraduate Scholarship.

The role of the bithorax complex (BX-C) in the genome of the fruitfly *Drosophila* is to specify the developmental pathways followed by cells in most of the insect's thoracic and abdominal segments¹. The BX-C has three lethal complementation groups, *Ubx*, *abd-A* and *Abd-B*, which have their major effects in progressively more posterior parts of the animal (Fig. 1)². Within the *Ubx* region³ there are four phenotypically distinct classes of mutations, *abx*, *bx*, *bxl* and *pbx*, each of which results in a part of the *Ubx* mutant phenotype^{1,4}. Here we show that these subfunction mutations all affect the distribution of *Ubx* proteins. The results support the view that the *Ubx* proteins represent the executive functions of the *Ubx* region⁵ and that the subfunction mutations affect regulatory regions required for the normal pattern of *Ubx* expression^{5,6}. In addition, we show that the region of the BX-C containing the *abd-A* and *Abd-B* complementation groups regulates the distribution of *Ubx* products.

The phenotype of *Ubx* mutations primarily affects four compartments: the posterior second thoracic compartment (T2p), the anterior third thoracic compartment (T3a), T3p and the anterior compartment of the first abdominal segment (A1a). In *Ubx* mutants, the sequence T2p T3a T3p A1a is transformed to

How do the subfunction mutations effect these transformations? Molecular analysis of the proximal region of the BX-C has revealed two transcription units⁵. One of these, the *Ubx* unit, is known to produce several transcripts and at least three

In *bx*³ third thoracic leg disks, *Ubx* protein expression is dramatically reduced in the anterior compartment (Fig. 2I). A similar effect is seen in the anterior compartment of the third thoracic dorsal disks (data not shown). In *pbx* third thoracic

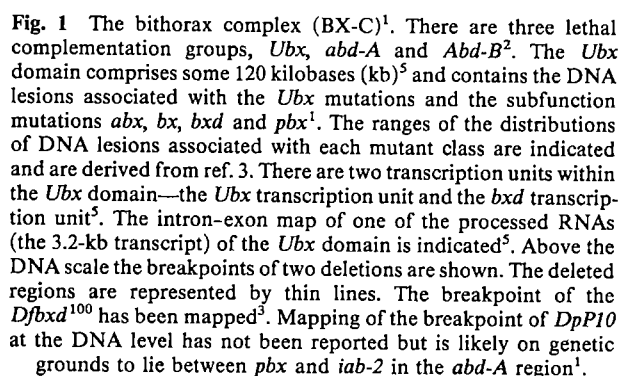

Figure 1 consists of 13 panels. Panels a, b, d, e, f, h, i, j, k, l, m, and n are fluorescence micrographs showing the development of ommatidia in the Drosophila eye. Panel g is a schematic diagram of an ommatidium, showing the arrangement of cells and the positions of the 'A' (accessory) and 'P' (pigment) cells. The panels are arranged in two rows: the top row contains a, c, e, g, i, k, m and the bottom row contains b, d, f, h, j, l, n. The micrographs show the progression from early stages (a, b) to later stages (m, n), with panel g providing a structural reference.

Methods. The immunofluorescence labelling of the disk whole-mounts has been described previously¹⁶. The disks were dissected from third-instar larvae and the homozygous mutant larvae were identified by using the balancer chromosome TM6B, constructed by L. Craymer and E. B. Lewis, which carries the dominant *Tb* marker. The *bx*³ homozygous third thoracic dorsal disks are not shown as they are necrosed.

ventral and dorsal imaginal disks, a complementary pattern is observed; there is a marked reduction in the level of *Ubx* protein expression in the posterior compartments (Fig. 2f, n). In neither case is there an effect on the labelling in the second thoracic disks. These results provide a molecular demonstration of the compartment-specific effect of the *bx*³ and *pbx* mutations and correlate with their compartment-specific effects on the adult cuticle^{11,12}.

The mutation *abx*² seems to resemble *bx*³ in its effect on *Ubx* protein expression in imaginal disks. In the third thoracic disks the most prominent effect is a reduction of the labelling in T3a in both the dorsal and ventral disks (Fig. 2d, j). However, the phenotype is more variable than *bx*³ and some disks exhibit patchy labelling in T3a and some dorsal disks also show patches of reduced labelling in T3p. This shows some correlation with the effects of *abx*² on the adult cuticle, where the most prominent effect appears to be a variable *bx*-like T3a → T2a transformation⁴. However, *abx* mutations also show a T2p → T1p transformation¹⁴ and thus the surprising aspect of the *Ubx* protein pattern in *abx*² is that this compartment seems to be unaffected.

Thus, these three subfunction mutations all affect the distribution of *Ubx* products in imaginal disks. The effects are correlated with the phenotypes of the mutants in the adult cuticle and may reasonably be supposed to be their cause. The mutations *abx*, *bx* and *pbx* therefore behave as if they affect regulatory functions required for the expression of *Ubx* products in specific areas. In the case of *bx* and *pbx*, these specific areas are T3a and T3p, respectively.

We have also examined the distribution of *Ubx* proteins in the nervous system, epidermis and mesoderm of mutant stage-13 embryos¹⁸. Here we will concentrate on the pattern of labelling in the ventral nervous system (VNS) as this is the most prominently labelled structure at this stage (Figs 3, 4). The wild-type pattern has been described previously^{5,16,17}. It exhibits a repeat unit, the *Ubx* metamere, which is out of phase with the segmental neuromere. The boundaries of the *Ubx* metameres may coincide with anterior/posterior compartment boundaries in the epidermis¹⁷ and thus *Ubx* metameres probably coincide with parasegments¹⁹. *Ubx* proteins are expressed in parasegments 5–13 in the VNS, with parasegment 6 being the most strongly labelled (Figs 4, 5).

In the embryos homozygous for the mutation *abx*², expression of *Ubx* products is reduced in parasegment 5 (Figs 4, 5). In the wild type the anterior region of parasegment 5 is more strongly labelled than the posterior. In *abx*² some labelling remains, particularly in the posterior region. However, our interpretation of the pattern is that the whole parasegment is affected. This agrees with the analysis of *abx* mutations on the commissure pattern in the VNS where *abx* mutations were observed to affect the pattern in both posterior T2 and anterior T3 (refs 14, 20).

The effect of *abx*² shows an interesting cell-type specificity. In the wild type the midline cells at the anterior edge of parasegment 4 (that is in T1) and those in T2 are labelled¹⁷. The labelling in T1 was unexpected, as the most anterior effect of *Ubx* mutations has been reported in the adult cuticle in T2p. The labelling pattern in the midline cells might be reconciled with the pattern in the rest of the VNS if the midline cells were to migrate one parasegment length anterior. In *abx*² the *Ubx* expression in the midline cells is unaffected (Fig. 4b). This result does not support the migration hypothesis, as in *abx*² there are two clusters of midline cells labelled anterior to the main block of labelling in the VNS. Rather, it indicates that the spatial control of *Ubx* expression in the midline cells differs from that in the rest of the VNS. Another example of cell-type specificity is the observation that *abx*² seems to have no effect on *Ubx* expression in the epidermis at this stage. The tissue-specific effect of *abx* over parasegment 5 suggests that it does not act to eliminate a compartment-specific product that is required to specify the T2p developmental pathway.

In contrast to the clear effect of *abx*², the mutations *bx*³ and *pbx* have no obvious effect on the distribution of *Ubx* products in either the VNS or the epidermis in stage-13 embryos. These

Fig. 3 Landmarks in the VNS—the commissure pattern. On the left is a dissected whole-mount of a stage-13 embryo labelled with fluorescein-coupled anti-horseradish peroxidase (HRP) antibody^{16,26}. This labelling reveals the pattern of transverse commissures (A/B and C) and lateral connectives in the VNS. On the right is an interpretation of the commissure pattern showing the segmental and parasegmental units. The head segments are represented by the supraoesophageal (S) and circular (Ci) commissures and posterior to this there is a repeat pattern of 14 parasegmental units^{17,19}. The boundaries of the parasegments are indicated on the right and probably coincide with the boundaries of the *Ubx* metameres in the VNS¹⁷. The boundaries of the *Ubx* metameres appear to lie on the anterior edge of commissure C (refs 16, 17). The segmental boundaries are indicated on the left and lie between commissure C and the succeeding A/B commissure²⁷. Md, mandibular; Mx, maxillary; Lb, labial.

mutations also have little or no effect on the commissure pattern in the VNS²⁰. We have also examined the *Ubx* pattern in the triple mutant *abx*¹ *bx*³ *pbx* and found that this shows a very similar pattern to *abx*². (In *abx*¹ *bx*³ *pbx* the reduction in *Ubx* expression appears to be more severe than in the *abx*². Whether this is due to the difference between the two *abx* alleles or to the influence of the *bx*³ and *pbx* mutations has not been investigated.) The lack of effect of the *bx* and *pbx* mutations at this stage contrasts with their clear effects on *Ubx* expression in imaginal disks and suggests that these mutations affect functions which are specifically required late in development or in the imaginal cell lineages.

While the subfunction mutations discussed above appear to reduce *Ubx* protein levels in rather specific locations, the effect of *Tpbxd*¹⁰⁰ extends over the whole range of the *Ubx* protein distribution⁵ (Figs 4, 5). Parasegments 5 and 6 are well labelled and, compared with the wild type, the labelling seems greater in the posterior part of parasegment 5 and less in parasegment 6. Parasegments 7–11 show an abnormal pattern, with fewer nuclei clearly labelled. There is a severe reduction in labelling from parasegment 11 to parasegment 12. In the wild-type a similarly severe reduction in labelling is seen between parasegment 12 and parasegment 13 (Fig. 5). This widespread effect of *bx*d mutations on *Ubx* expression correlates with their extensive phenotypic effects¹.

The second type of regulation that we have investigated is the influence on *Ubx* protein distribution of the centromere-distal region of the BX-C, containing the *abd-A* and *Abd-B* complementation groups. Deletion of this distal region in *DpP10;DfP9* homozygotes results in a transformation of parasegments 7–13 to parasegment 6 (refs 1, 10). If high-level *Ubx*

Fig. 4 *Ubx* protein expression in the VNS in wild-type and mutant stage-13 embryos. Dissected embryo whole-mounts were labelled with FP.3.38 to reveal *Ubx* proteins and with anti-HRP to reveal the commissure pattern. The parasegmental boundaries are indicated and are derived by superimposition of the anti-HRP pattern on the FP.3.38 pattern. *a*, Wild type. The *Ubx* proteins are expressed in parasegments 5–13. The most prominent expression is in parasegment 6. The labelling declines posteriorly and drops sharply in parasegment 13 where only four nuclei are well labelled at this stage. *b*, *abx*² homozygous embryo. The labelling is wild type apart from a reduction in parasegment 5. Note that the midline cells anterior to parasegments 4 and 5 are unaffected. *c*, *abx*¹, *bx*³ *pbx* homozygous embryo. Similar to *b* but slightly greater reduction of labelling in parasegment 5. *d*, *Tpbxd*¹⁰⁰. Altered pattern in parasegments 5–13. Note parasegments 5 and 6 are very similar. Compared with wild-type, fewer nuclei are clearly labelled in parasegments 7–11. Parasegment 12 shows a pattern similar to wild-type parasegment 13. *e*, Homozygous *DpP10; DfP9* embryo. This mutation leaves the *Ubx* domain intact but removes *abd-A* and *Abd-B* (see Fig. 1). Parasegment 5 is unaffected, but parasegments 6–13 exhibit the wild-type pattern of parasegment 6. *f*, *Pc*³ homozygous embryos. There is labelling over the whole VNS. Although labelling intensity declines from anterior to posterior, most parasegments exhibit a pattern similar to that seen in wild-type parasegments 7–12.

Methods. Embryos were dissected from heterozygous stocks and labelled as described previously¹⁶. The stocks and the fraction of embryos showing the mutant phenotypes illustrated above were: *abx*²/TM1, 8/41; *abx*¹ *bx*³ *pbx*/TM1, 12/36; *Tpbxd*¹⁰⁰/TM1, 11/42; *DpP10; DfP9*/TM1, 7/31; *Pc*³/TM1, 5/36. The above frequencies are all consistent with the expected 1/4 homozygous mutant progeny. Of 24 embryos from *bx*³/TM1 stocks and 29 embryos from *pbx*/TM1 stocks, none showed any clear deviation from the wild-type pattern.

expression is a prerequisite for the parasegment 6 developmental pathway, then in *DpP10; DfP9* homozygotes parasegments 7–13 should express high levels of *Ubx* protein, and this is indeed what we find (Figs 4, 5). Thus it appears that in the wild type, *abd-A* and/or *Abd-B* regulate *Ubx* protein distribution in parasegments 7–13. Such interactions between homoeotic genes have been proposed²⁸ and the regulation of the distribution of *Antennapedia* transcripts by genes in the BX-C has provided a clear example²¹. This interaction is investigated and discussed more fully elsewhere²².

We would like to note here how this interaction contributes to our understanding of other mutant effects. The first is tentative and concerns the *Tpbxd*¹⁰⁰ phenotype. In embryos homozygous for *Tpbxd*¹⁰⁰, the effect on *Ubx* product distribution shares two features with the *DpP10; DfP9* effect in that many segments are affected and the pattern is altered in both VNS and epidermis. In addition, the sharp decrease in *Ubx* protein level in the wild-type pattern in parasegment 13 occurs in parasegment 12 in the *Tpbxd*¹⁰⁰ pattern. The decrease in wild-type parasegment 13 is part of the regulation of *Ubx* product distribution by genes in the centromere-distal region of the BX-C, as it is not observed in *DpP10; DfP9* embryos (see also ref. 22). These features suggest that an important part of the effect of *Tpbxd*¹⁰⁰ on *Ubx* protein distribution may be its effect on the interactions between homoeotic genes.

The second case is the effect of *Polycomb* (*Pc*) on *Ubx* protein distribution. The labelling pattern in the VNS of homozygous *Pc*³ embryos is shown in Figs 4 and 5 and is similar to that reported previously⁵. The whole of the VNS is labelled, and although the intensity of labelling is quite variable, it generally tends to be higher anteriorly and to tail off posteriorly. The *Pc* gene has been postulated to act as a repressor of BX-C genes¹ and thus in *Pc* mutant embryos *Ubx* should be derepressed. However, *Ubx* protein products are not expressed at the high level found in parasegment 6 in the wild type. This is readily explained if the other genes of the BX-C are also expressed along the length of the animal in *Pc* embryos. The regulation of *Ubx* protein expression by *abd-A* and/or *Abd-B* (perhaps together with other homoeotic genes) then results in the observed ubiquitous moderate level of *Ubx* protein expression.

Our results support the model that the *Ubx* proteins represent the executive functions of the *Ubx* complementation group⁵, as the subfunction mutations all affect the distribution of *Ubx* products. The subfunction mutations appear to map outside

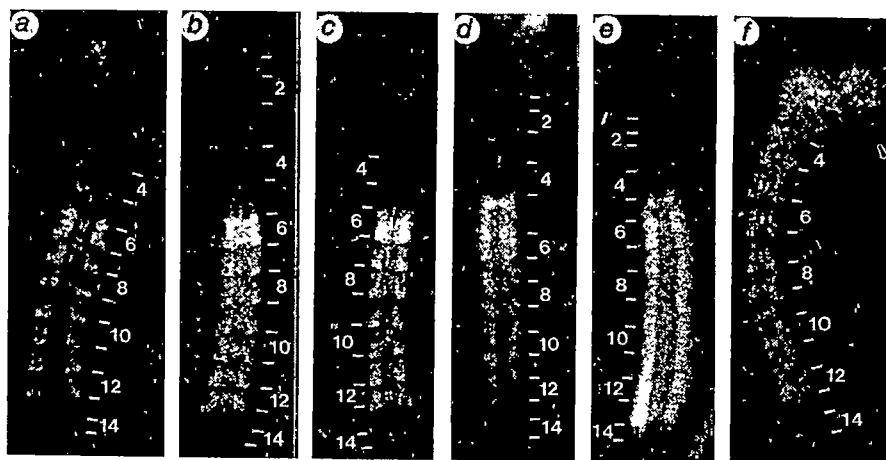

Fig. 5 Schematic diagram of *Ubx* protein expression in the VNS in wild-type and mutant embryos. The parasegmental units are indicated at the sides of the figure (see Fig. 4 for descriptions). *Dfbxd*¹⁰⁰ homozygous embryos lack the *Ubx* domain but contain the *abd-A* and *Abd-B* regions (see Fig. 1). They exhibit no labelling with FP.3.38 (ref. 16).

known coding sequences for *Ubx* products^{3,5} and behave as mutations in *cis*-regulatory sequences¹¹. However, it is not clear to what extent the specificity of their effects reflects the existence of specific wild-type regulatory functions rather than being a property of the mutations themselves. It has already been noted that the subfunction mutations differ in the nature of their DNA lesions as well as in their location³. For example, most *bx* mutations that have been examined are insertions of the *Gypsy* transposable element³ and developmentally regulated activity of the *Gypsy* promoter elements²³ may be important for their specific phenotypes.

Investigation of the patterns of *Ubx* transcript¹⁵ and protein¹⁷ distribution in wild-type embryos and larvae suggests a complex

programme of spatial and temporal control. Although we know little about the regulation of these patterns, we have established here that, in the stage-13 embryo, interactions between the genes of the BX-C have an important role. The key to understanding the subfunction effects may well lie in the interactions regulating the pattern of *Ubx* expression rather than in the individual *Ubx* products.

Contrabithorax mutations cause inappropriate expression of Ultrabithorax products in *Drosophila*

Robert A. H. White & Michael E. Akam*

MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

* Department of Genetics, University of Cambridge, Downing Street, Cambridge CB2 3EH, UK

The mutation *Contrabithorax* (*Cbx*) has played an important part in the recognition of the role that genes of the bithorax complex (BX-C) play in the control of development. *Contrabithorax*, a dominant mutation which maps in the proximal or Ultrabithorax domain of the BX-C, results in the transformation of structures of the second thoracic segment (T2) into homologous structures of T3 (ref. 1). Recessive mutations and deletions of the same chromosome region have the reverse effect, transforming T3 into T2. This reciprocal relationship between the effects of dominant (gain of function) and recessive (loss of function) mutations suggested that products of the BX-C were both necessary and sufficient to specify the unique developmental pathways of different segments². Here we report that the original *Contrabithorax* mutation (*Cbx*¹) and two other dominant mutations in the Ultrabithorax domain, *Cbx*³ (ref. 3) and *Haltere mimic* (*Hm*)^{3,4}, all cause the inappropriate expression in T2 of products from the *Ultrabithorax* (*Ubx*) transcription unit. This strongly supports the suggestion that these products execute the functions of the proximal or Ultrabithorax domain of the BX-C⁵.

The DNA lesion in *Cbx*¹ is an insertion of ~17 kilobases (kb) into intron sequences of the *Ubx* transcription unit. The inserted sequences duplicate, in inverse orientation, a region normally located 27-44 kb upstream from the *Ubx* transcription start site^{5,6}. Two models have been proposed to explain the effects of this lesion on the development of cells in T2 (ref. 6). The first model suggests that the inserted DNA encodes a function that is required for the development of T3. The new location of this DNA fragment in the *Cbx*¹ mutation may then induce the inappropriate expression of this function in cells of T2, causing them to follow the T3 developmental pathway. The second model suggests that the *Cbx*¹ insertion interferes with the normal spatial regulation of the *Ubx* transcription unit itself, and that it is the inappropriate expression of *Ubx* products in T2 which changes the developmental pathway of these cells.

We have approached this question by examining the distribution of *Ubx* transcripts and proteins in the wing imaginal disks of larvae homozygous for the *Cbx*¹ mutation. In the wild type, there is little expression of *Ubx* in the wing disks (which will give rise to most of the dorsal structures of T2 in the adult), but *Ubx* transcripts and proteins are relatively abundant in the homologous disks of T3, which will give rise to the haltere, and in the T3 leg disks^{7,8}. In *Cbx*¹ homozygotes, *Ubx* transcripts and proteins are expressed in regions of the wing disk at levels comparable with those found in the normal T3 disks (Figs 1, 2).

The patterns of *Ubx* expression can best be seen in whole-mounts of wing disks which have been labelled for *Ubx* proteins (Fig. 2). Although details of the protein distribution vary from disk to disk, a high level of *Ubx* proteins is usually observed throughout most of the posterior compartment of *Cbx*¹ wing disks, with patches of expression also in the anterior compartment. This distribution correlates well with the cuticular phenotype seen in adults homozygous for the *Cbx*¹ mutation⁹. The posterior compartment of the second thoracic appendage is frequently transformed to T3, whereas the anterior compartment is transformed less frequently, and only in patches. This correspondence between cuticular phenotype and the expression of *Ubx* strongly suggests that the inappropriate expression of *Ubx* products is the cause of the observed transformations.

We have also examined the distribution of *Ubx* products in wing disks carrying the *Cbx*³ and *Hm* mutations. Both of these mutations have phenotypes analogous to that of *Cbx*¹, but the regions of T2 which are transformed to T3 are different for each of the three mutations³. *Cbx*³ results in a variable transformation which at its most extreme affects the entire anterior compartment of the wing and notum, but does not transform the posterior compartment (Fig. 3). *Ubx* proteins are also expressed in variable, but often extensive, regions in the anterior compartment of the *Cbx*³ wing disks, and the boundary of *Ubx* expression frequently defines a line at or close to the location of the anterior/posterior compartment boundary. The *Hm* mutation has a much more uniform phenotype: the entire wing blade is transformed to haltere tissue, but the notum is unaffected. In this case, a relatively constant pattern of *Ubx* expression is observed in the wing disk. Regions of the disk which will form the wing blade express high levels of *Ubx* proteins, but specific cells in other regions of the disk also express *Ubx* (Fig. 2).

None of these is simply a 'constitutive' mutation, resulting in the indiscriminate expression of the *Ubx* gene. In the case of *Cbx*¹ the only structures of the third-instar larva in which we have seen an effect of the mutation are the T2 dorsal and ventral disks. In other disks (for example, eye-antennal), and in other tissues, which do not normally express *Ubx* (for example, brain lobes, midgut), neither *Ubx* transcripts nor proteins are detectable (Fig. 1 and data not shown). Abnormally high levels of *Ubx* products are observed, however, in parasegment 5 of the embryonic nervous system (data not shown). In the case of *Hm* we have seen the inappropriate expression of *Ubx* in certain epidermal cells other than the wing disks, including cells of the anterior spiracle, but not in endoderm or most other tissues.

It is not yet clear how the effects of these dominant 'gain of function' mutations relate to the normal spatial regulation of

Fig. 1 Hybridization of *Ubx* probes to *Cbx* and *Hm* tissue sections. *a, b*, Bright- and dark-field photograph, respectively, of an autoradiograph of a horizontal section through the anterior of a wild-type third-instar larva. The *Ubx* probe hybridizes to the haltere disks (*h*) of T3, but not to the wing disks (*w*) of T2, nor to the eye-antennal (*ea*) disks or brain (*br*). (See ref. 7 for further details of the wild-type pattern.) *c, d*, Bright- and dark-field views of a comparable autoradiograph from a *Cbx*¹/*Cbx*¹ larva. The outlines of structures visible in this section are indicated in *e* and the boxed region is shown enlarged in *f*. The *Ubx* probe hybridizes to the disks of T3 (haltere and third leg (*l*₃), and also to regions of the wing disk, but not to eye-antennal disks or brain. *g*, Wing disk from *Cbx*¹/*Cbx*¹ third-instar larva, showing extensive transcription of *Ubx*. *h*, Wing disk from a *Hm*/+ third-instar larva, again showing a large region of *Ubx* transcription. Scale bars: *a-d*, 100 μ m; *f-h*, 50 μ m.

Methods. Probe preparation and hybridization conditions were as described in Fig. 3 legend of ref. 7. Note that the hybridization probe used is single-stranded (synthesized on the M13 template A113), and will therefore hybridize only to 5'-3' transcripts from the 5' exon of the *Ubx* transcription unit, and not to any transcripts originating from a promoter in the DNA of the *Cbx*¹ insertion, which would traverse the *Ubx* 5' exon in reverse orientation. Autoradiographic exposures were as follows: *a, b*, 15 days; *c-h*, 24 days.

Fig. 2 *Ubx* protein expression in wild-type and mutant wing imaginal disks. In the upper line the disks are labelled with the DNA-binding dye Hoechst 33258 to reveal the total pattern of nuclei. In the lower line the disks are labelled with the monoclonal antibody FP.3.38 to reveal the pattern of *Ubx* protein expression (see ref. 8 for details of this procedure). The disks are oriented with the anterior compartment on the left. *a, b*, Wild type. There is weak labelling on the posterior side of the disk, principally in the widely spaced nuclei of the peripodial membrane. *c-f*, *Cbx*¹/*Cbx*¹ disks. In *d* the labelling appears to fill the posterior compartment of the disk and the label boundary correlates well with the position of the anterior/posterior compartment boundary¹³. A more complex pattern is observed in the disk shown in *e* and *f*. It is not clear whether the entire posterior compartment is labelled, and there is patchy labelling in the anterior compartment. *g-j*, *Cbx*³/+ disks. In *h* the labelling appears to be restricted to the anterior compartment and, within this, principally in the presumptive distal region of the disk. The sharp boundary in the distal region probably coincides with the anterior/posterior compartment boundary. The disk in *j* shows an example of less extensive expression. The sharp boundaries of *Ubx* protein expression in *h* and *j* coincide with morphological discontinuities visible in the Hoechst-labelled disks (but barely discernible in these photographs, *g* and *i*). Thus, in *g* there is a single discontinuity corresponding to the single boundary of *Ubx* expression in *h*, and in *i* there are two discontinuities in the central distal area corresponding to the boundaries in *j*. Presumably, these discontinuities reflect cell-surface differences under *Ubx* control. *k, l*, *Hm*/+ disks: *Ubx* proteins are expressed in a complex pattern, mostly over the distal region of the disk. Other *Hm*/+ disks examined showed a very similar pattern of *Ubx* protein expression.

Fig. 3 The wing of a *Cbx*³/+ fly. Anterior is at the top and the proximal regions are to the left. The transformation of anterior structures is virtually complete in the distal regions, where the cuticle is covered with small, densely packed trichomes characteristic of the haltere. Proximally, the transformation is less complete, with many wing hinge structures remaining.

the *Ubx* gene. In the case of *Cbx*¹, there is reason to believe that the effect of the mutation on *Ubx* expression does reflect, in an aberrant way, the normal functions of the transposed DNA sequences. The *Cbx*¹ insertion arose together with a reciprocal deletion of *Ubx* upstream sequences, and was only subsequently separated by recombination¹⁰. Deletion of these sequences generates a *postbithorax* mutation¹⁰, which greatly reduces *Ubx* expression in the posterior part of the haltere disk¹¹. Thus, the deletion and relocation of these *Ubx* upstream sequences have virtually reciprocal effects on *Ubx* expression, suggesting that the transposed element normally has a role in the regulation of *Ubx*, principally in posterior compartments.

The *Cbx*³ mutation probably affects a different regulatory element. The only DNA lesion detected in this chromosome is an inversion break at the extreme 3' end of the *Ubx* transcription unit, 60 kb from the site of the *Cbx*¹ insertion⁶. This mutation allows the expression of *Ubx* in a region where it is normally never active, but has little or no effect on the expression of *Ubx* in those regions where it is normally active; flies homozygous for the *Cbx*³ mutation survive, and are virtually normal in T3 and A1 (M.E.A., unpublished observations). A second mutation with a very similar phenotype (*Cbx*^{nov}) proves to be an inversion with one break at virtually the same site in the BX-C⁶; this suggests that both mutations affect a regulatory element located near the 3' end of *Ubx* which is involved in the repression of *Ubx* in the region immediately anterior to its normal domain of expression.

The *Hm* mutation is associated with a chromosome rearrangement broken within 4 kb of the *Ubx* transcription start site¹², suggesting that it may result from the fusion of unrelated upstream elements to the *Ubx* gene.

These three dominant mutations, of very different structure, are alike only in that they result in the expression of *Ubx* proteins in the wing disk. It seems likely that any DNA rearrangement which has this effect, however fortuitously, will result in a 'Contrabithorax' phenotype.

We thank E. B. Lewis for providing fly stocks, and Helen Moore and Richard Smith for assistance. This work was supported by the MRC. R.A.H.W. is the recipient of a Beit Memorial Fellowship.

Distribution of *Ultrabithorax* proteins in mutants of *Drosophila bithorax* complex and its transregulatory genes

Carlos V. Cabrera, Juan Botas & Antonio Garcia-Bellido

Centro de Biología Molecular, CSIC, Universidad Autónoma de Madrid, 28049 Madrid, Spain

The phenotypic effects of mutations have classically been described in terms of their penetrance, expressivity and specificity¹. These three parameters can give insights into the wild-type function of the genes affected by the mutations; for example, the topographic specificity of homeotic mutations provides a crucial clue to our understanding of the normal function of homeotic genes in development. The null alleles of such genes have constant specificity², and the expectation is that these genes are expressed in all the cells of the compartments affected by their mutations. However, hypomorphic mutations of the 'selector' genes that specify compartment identity are also known which have only partial, and sometimes variable, specificity. We have now studied the distribution of protein products of the *Drosophila Ultrabithorax* (*Ubx*) gene in various mutants, both of the *Ubx* domain of the bithorax complex and of *trans*-regulatory genes predicted to affect *Ubx* expression³. We find that the topographical specificity of the mutations correlates with the distribution of *Ubx* protein. In particular, in partially transformed compartments we find sharp within-compartment variation in the level of *Ubx* protein expression. This may correspond to alternative steady states of gene activity established by cell-cell interactions, which we suggest may reflect processes of normal development involved in embryonic compartmentalization.

The *Ubx* products were visualized by immunofluorescence using a monoclonal antibody specific for the protein products of the common 5' exon of the *Ubx* transcription unit⁴. The distribution of the *Ubx* proteins was studied in imaginal disks of mature larvae. Positive label only indicates the presence of at least one of the *Ubx* products and negative label indicates the absence of all or the most abundant proteins⁴. Fate maps of the imaginal disks considered here, the wing and haltere disks^{5,6}, allow us to correlate the adult transformation with the distribution of *Ubx* products in the mutant imaginal disks (Fig. 1a).

Previous studies using this antibody have shown that the *Ubx* proteins have a non-homogeneous distribution in the wild-type imaginal disks⁷, something not expected on the basis of mutational analyses. Thus, *Ubx* proteins appear in both compartments of the haltere disk, but show a more extreme label in the posterior one. Even within compartments, certain regions regularly show more label than others (Fig. 1c). *Ubx* label also appears in the pleural region of the posterior compartment of the wing disk⁴ (Fig. 1b). This is expected because *Ubx* mosaics show transformations in the posterior mesopleura^{8,9}.

The *Ubx* domain can be subdivided into two regions. One codes for RNAs that become translated into different proteins, the *Ubx* transcription unit, while the second is a *cis*-regulatory region coding for several RNAs, possibly involved in the differential splicing of the *Ubx* transcripts¹⁰; it is in this region that *postbithorax* (*pbx*) and *bithoraxoid* (*bxd*) mutations map¹¹.

We have analysed the distribution of *Ubx* products in several mutants of the *Ubx* region. One of them, *bx*^{34c}, shows, with variable expressivity but constant specificity, partial transformations to anterior wing and mesonotal structures in the dorsal metathorax⁸. This transformation is associated with an enlarged haltere in the presumptive wing territory (compare Fig. 1c with 1d). Figure 1d shows an example of the *Ubx* products in the transformed *bx*^{34c} haltere disks. The pattern of immunofluorescence varies slightly between imaginal disks of the same genotype. It holds for all cases observed, however, that distinct patches with only weak (and in some cases absent) label

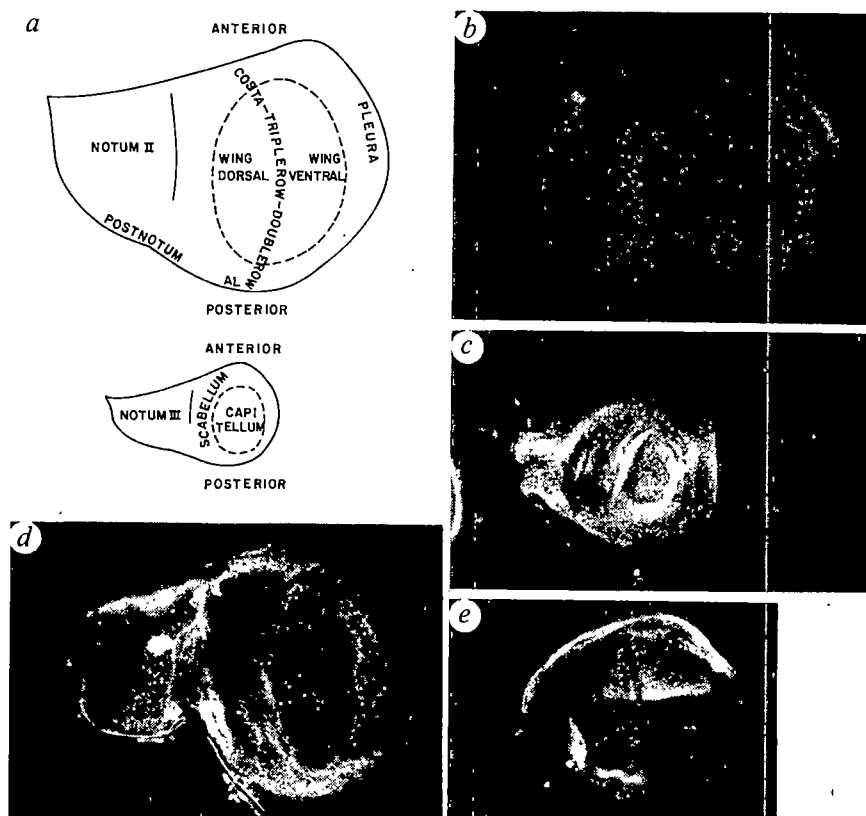

Fig. 1 Immunofluorescence patterns of *Ubx* expression. *a*, Fate maps of wing and haltere imaginal structures^{5,6}. Upper is anterior and lower posterior throughout. *b*, Wild-type wing disk; ventral view showing the posterior peripodial membrane (pleura) positively stained. *c*, Wild-type haltere disk. *d*, *bx*^{34e}/*Df*(3*R*)*Ubx*¹⁰⁹-transformed haltere disk with dark patches of unlabelled tissue in the anterior compartment. *e*, *pbx*¹/*Df*(3*R*)*Ubx*¹⁰⁹-transformed haltere disk with a large fraction of the posterior compartment showing negative staining. Note the positive label of the peripodial membrane.

Methods. Larvae were obtained from outcrosses of stocks balanced with *TM6B*, carrying a dominant marker (*Tubby*) to distinguish the genotypes to be studied. Third-instar larvae were dissected in TBS (50 mM Tris pH 7.4, 150 mM NaCl), disks mounted in polylysine-coated slides and further treated as described elsewhere⁶. The first antibody was FP3.38 ascites fluid used in a 1:200 dilution. The second antibody was goat anti-mouse IgG conjugated to fluorescein (Sigma) used at 1:50 dilution. Slides were mounted in glycerol-propylgallate-TBS and photographed with Ektachrome 400 ASA film in a Nikon microscope using filter set IF460-485. All major disks and salivary glands were studied from each mutant. Several individuals (4–10) in each case were dissected to ascertain the constance of the pattern. Controls of wild-type and *Df*(3*R*)*Ubx*¹⁰⁹/+ disks were run in parallel. The latter genotype consistently showed a slightly reduced intensity of staining.

Fig. 2 Immunofluorescence patterns of *Ubx* expression. *a*, *T*(2;3)*Hm*/+ transformed wing disk. The positive label in the wing blade corresponds with the adult transformation to capitulum, the spots of label observed on the presumptive notum are due to *Ubx*-positive cells of the trachea. *b*, *Cbx*¹/+ transformed wing disk. The positive label appears in discrete patches in the posterior wing region. *c*, *Pc*³*Dp*(3;3)*P5*/+ wing disk with spots of positive label in the posterior region. *Dp*(3;3)*P5* is a tandem duplication of the entire bithorax complex (BX-C). Extra copies of the BX-C enhance the *Cbx*-like phenotype produced by *Pc* mutations, but never show mutant phenotype in *Pc*⁺ flies. The black hole in the middle of the disk is due to an air bubble. *d*, *Df*(3*R*)*red*^{P52}/*Rg-bx*^{trxA} (*Rg-bx*^{trxA}) (M. P. Capdevila, unpublished) haltere disk with patches of negative staining in the anterior region.

(Fig. 1*d*) appear in regions of the anterior compartment, corresponding in position and extent to the wing-transformed territories of the adult dorsal metathorax. The boundaries between strong and weak (or absent) signal are very precise, although along them some cells with intermediate levels of label can also be seen. Cell lineage analysis of *bx*^{34e} mutant halteres shows that even small clones, generated late in development, can include both wing bristles and trichomes with haltere characteristics. The boundaries between these two types of tissue result from late developmental decisions in cells unrelated by lineage, that is, the transformation is not clonal (G. Morata and P. A. Lawrence personal communication, and unpublished observations of this laboratory).

The *pbx* mutants show, with variable expressivity and constant specificity, transformation of posterior haltere to posterior wing structures⁵. The *pbx*¹ haltere disks (Fig. 1*e*) show sharp boun-

daries between the putative transformed (enlarged) and non-transformed tissue. The distinct patches, which here are devoid of label, correspond in position and extent to the adult wing transformations (see also ref. 12). The absence of label observed in *pbx*¹ haltere disks supports the hypothesis that the *pbx*-*bx**d* region regulates *Ubx* in *cis* (refs 10, 13). We do not know whether the *pbx* transformations are of clonal origin.

Dominant mutations due to gain of function of the *Ubx* gene are generically designated *Contrabithorax* (*Cbx*). They are associated with molecular alterations in the DNA, within (*Cbx*¹) or near (*Hm*: *Haltere mimic*) the *Ubx* coding region (ref. 11 and W. Bender, personal communication). All the known *Cbx* mutants differ in specificity. We present here data for *Cbx*¹ and *Hm* (ref. 14 and Fig. 2). *Cbx*¹ heterozygotes show, with variable expressivity and constant specificity, a transformation of mainly the posterior wing into posterior haltere tissue, with smooth

boundaries. This transformation is not clonal¹⁵. *Hm* / +, on the other hand, presents distal (both anterior and posterior) compartments of the wing transformed into haltere tissue (capitulum). The histotypical borders are rather sharp, but the transformation is not clonal, at least from early stages of development (M. P. Capdevila, personal communication). The mutant wing disks of both *Cbx*¹ and *Hm* retain positive label in pleural regions but also have *Ubx* products in the regions that correspond to the transformations observed in the adult (Fig. 2a, b). In both cases, sharp boundaries can be observed between labelled and unlabelled cells. A pattern of label similar to that of wild type has been detected in the mesothoracic leg disk (labelled) and in the more anterior thoracic or cephalic eye-antennal disk (no label). The heterozygotes for these mutations show a normal pattern of *Ubx* products in both haltere and metathoracic legs.

The non-clonality of *bx* and *Cbx* transformations shows that they do not result from early segregation of lineages of cells. The adult mosaic transformations probably result from interactions between neighbouring cells during the development of the imaginal disks. The discontinuity of *Ubx* label observed in alleles causing either loss or gain of function corresponds to strong quantitative differences in *Ubx* products. These boundaries probably reflect discontinuity of territories with cells in either of two steady states—one typical of full expression of the *Ubx* gene, the other of lack of *Ubx* products. This reinforcement/extinction pattern of expression in neighbouring, genetically identical cells further suggests that regulatory mechanisms are involved in the maintenance of gene activity. Therefore, we studied the pattern of expression of *Ubx* products in flies mutant for two *trans*-regulatory genes of *Ubx*; these were *Polycomb* (*Pc*)^{16,17} and *Regulator of bithorax* (*Rg-bx*)^{18–20}.

Mutations in *Pc* cause a *Cbx*-like transformation in the wing of heterozygotes and mutations in *Rg-bx* cause *bx*-like transformations in the halteres of heterozygotes. The *Cbx*-like phenotype produced by *Pc* is of variable expressivity but of constant specificity; haltere tissue appears in the posterior wing border and gradually goes into wing tissue. This transformation is not clonal¹⁷. The *Ubx* label of *Pc*³ wing disks appears as multiple scattered spots in the presumptive region of the adult transformations, against a wild-type unlabelled background (Fig. 2c). The transformations caused by *Rg-bx* mutations are of variable penetrance, full expressivity but erratic specificity¹⁸. These transformations are not clonal, at least from early stages of development²⁰. The haltere disks of *Rg-bx* mutants show erratic patches of unlabelled tissue, separated by sharp boundaries from fully labelled territories (Fig. 2d). The patches appear restricted to the anterior compartments of haltere disks as are the transformations seen in the adult cuticle.

Genetic arguments suggest that both *Pc* and *Rg-bx* genes are involved in the regulation of *Ubx* expression both in embryogenesis and during imaginal cell proliferation^{3,19,21}. The genetic model suggests that *Pc*⁺ acts as a repressor and that *Rg-bx*⁺ has a positive role in the expression of *Ubx* (ref. 21 and J.B. and A.G.-B., unpublished data). The present results support these arguments and indicate further that these genes could be involved in the reinforcement/extinction process suggested above. Since both *Pc* and *Rg-bx* transformations are not clonal, the reinforcement/extinction process must extend to neighbouring cells. We do not know the polarity of these influences (expressing as opposed to non-expressing cells), neither do we know which are the genes of the syntagma involved in these interactions. Possibly these mechanisms also affect selector gene expression in regeneration and *trans*-determination²².

Our results indicate that cell interactions must be involved in determining the spatial patterns of expression during imaginal disk cell proliferation. In addition, we postulate that the same mechanisms also take place in early specification. *Ubx* transcripts appear in blastoderm stages, first as uniformly distributed over the presumptive mesothorax, metathorax and first abdominal segments, and later becoming restricted to posterior mesothorax, metathorax and anterior first abdominal²³. The

extinction in the mesothorax is not complete, but remains in the posterior pleural cells. We postulate that *Cbx* mutations affect this process of spatial restrictions, retaining in part the early embryonic pattern of transcription. Why this pattern is retained in an allele-specific manner in the different *Cbx*-like mutations is not known. The reinforcement/extinction process in mutants with partial loss of function is also reminiscent of the mechanisms involved in compartment specification. Early diffused patterns of transcription over several compartments become sharply delineated in the cells of wild-type individuals, as imaginal cells mutant for hypomorphic alleles do within compartments during proliferation. Again, we do not know why these patterns are allele-specific topographically. Indeed, pattern specificity, in both normal and mutant organisms, remains the most elusive problem in developmental genetics.

We thank R. White for FP3.38 antibody, P. Ripoll for critically reading the manuscript and the Spanish CAICYT and FIS for financial support.

Identification of the gene responsible for human T-cell leukaemia virus transcriptional regulation

Alan J. Cann, Joseph D. Rosenblatt, William Wachsman, Neil P. Shah & Irvin S. Y. Chen

Division of Hematology-Oncology, Department of Medicine and Jonsson Comprehensive Cancer Center, UCLA School of Medicine, Los Angeles, California 90024, USA

Human T-cell leukaemia viruses (HTLVs) have genomic organization distinct from that of other replication-competent retroviruses, possessing four genes, *gag*, *pol*, *env* and χ . The unique fourth gene, χ (also referred to as *lor*), is located between *env* and the 3' long terminal repeat (LTR), encoding a protein of relative molecular mass 40,000 for HTLV-I and 37,000 for HTLV-II^{1,2}, located in the nucleus of infected cells^{3,4}. HTLV-I is the causative agent of adult T-cell leukaemia (ATL), a T-lymphocyte malignancy^{5,6}, while HTLV-II has been found associated with a T-cell variant of hairy cell leukaemia^{7,8}. Both viruses immortalize T cells *in vitro*^{9–11}. However, the mechanism of cellular transformation induced by HTLV is not known as there seems to be no common site of provirus integration in primary ATL cells¹² and the virus contains no classical oncogene sequences^{13,14}. These observations have provoked speculation that the unique and strongly conserved χ protein (85% amino-acid homology between HTLV-I and -II) is involved in HTLV leukaemogenesis. Recent mutagenesis experiments in our laboratory have shown that the χ gene is essential

for HTLV replication¹⁵. It has also been shown that the LTRs of HTLV and the related bovine leukaemia virus (BLV) are activated *in trans* in virus-infected cells¹⁶⁻¹⁹, and, although such experiments did not directly demonstrate a role for the χ protein in transcriptional activation, it has been suggested that the χ protein is responsible for the transcriptional activation of the LTR and may be involved in cellular transformation^{3,4,16}. We have now developed a transient co-transfection assay which demonstrates that transcriptional activation of the HTLV LTR is mediated solely by the χ protein and that no other virus genes are required.

Others who have examined transcriptional regulation of the LTRs of HTLV or BLV have used constructions where transcrip-

tion from the LTR is measured by chloramphenicol acetyl transferase (CAT) activity following transfection of virus-infected cells¹⁶⁻¹⁹. We have used a highly sensitive transient co-transfection system to study activation of the LTR where selection of infected or transformed cells would not affect the results obtained. This system has the further advantage that the effects of individual virus genes can be isolated both from one another and from effects seen in immortalized virus-infected cells.

Figure 1 shows the schematic structure of the HTLV transcriptional units in pH6neo, cH6-H11, SV-HTLV and SV-3.9. In pH6neo and cH6-H11, both of which contain a complete provirus genome from the infectious HTLV-II clone λ H6 (ref. 20), transcription of HTLV-II genes would be expected to occur from the native cap site in the 5' LTR. In SV-HTLV, the HTLV insert is an 8.2-kilobase (kb) *Bam*HI fragment of the virus which extends from the 5' LTR to the 3' LTR but lacks the 5' 361 nucleotides (U3 and part of the R region) and 3' 462 nucleotides (part of R and U5) of the HTLV-II genome. The viral genes are expressed using simian virus 40 (SV40) transcription sequences present in the vector. Removal of the HTLV promoter region from the U3 portion of the 5' LTR and HTLV termination sequences from the 3' LTR results in transcription being promoted by the upstream SV40 promoter-enhancer region and terminated in the SV40 termination-polyadenylation sequences downstream of the HTLV insert. SV-3.9 has a 3.9-kb fragment of HTLV-I which extends from genomic position 4,990 in the *pol* gene to near the 3' end of the provirus genome and encodes all of the sequences necessary for χ gene expression²¹. Transcription is promoted by the upstream SV40 promoter-enhancer region of the vector, as is the case with SV-HTLV, but terminates in the 3' LTR rather than in the SV40 sequences of the vector (Fig. 1).

Figure 2a shows the results of co-transfections in COS cells with each of these constructions and either HTLV-I LTR-CAT (LTR-I-CAT) or HTLV-II LTR-CAT (LTR-II-CAT)^{15,22}. Transcriptional activation of the LTR-CAT constructions occurs

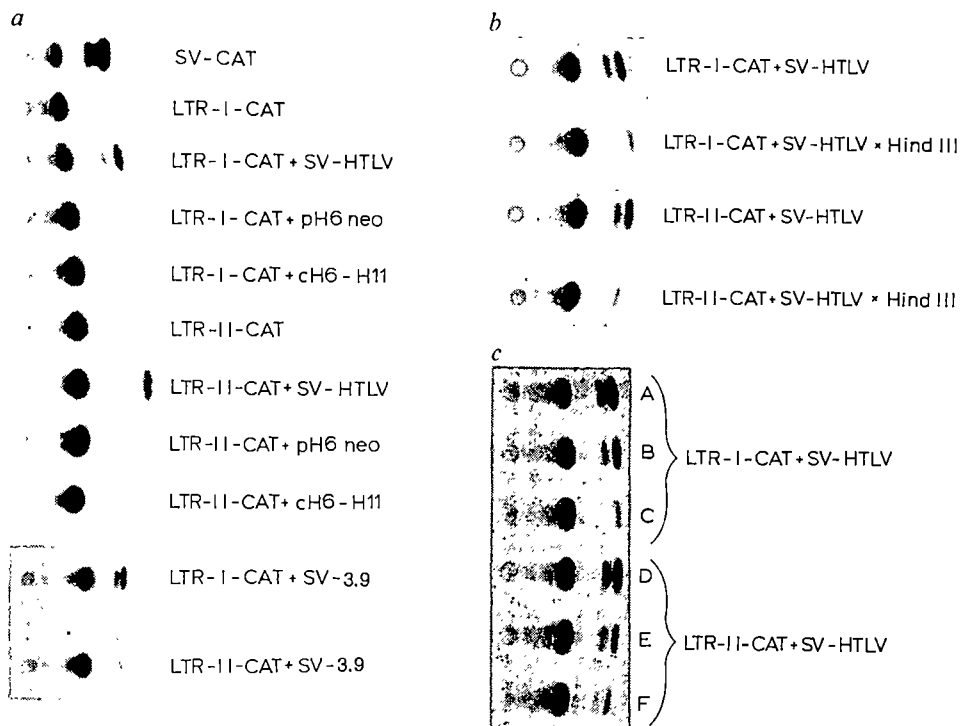

Fig. 1 Schematic structure of constructions used in transfection experiments. Upper line: HTLV-II insert of pH6-neo in the vector pSV2-neo (ref. 34) and cH6-H11 in the vector pSVod (ref. 35). The entire HTLV-II genome (8.9 kb) plus some flanking cellular DNA is present in both constructions. Middle line: structure of construct SV-HTLV, which has an 8.2-kb HTLV-II insert (nucleotide positions 362-8,550) in vector pSV2-neo. The 8.2-kb fragment from a partial *Bam*HI digestion was treated with the large fragment of *Escherichia coli* DNA polymerase I. *Hind*III linkers were added and the fragment was ligated to *Hind*III-digested pSV2-neo. Lower line: structure of construct SV-3.9. A 3.9-kb fragment from the 3' end of the HTLV-I genome (from a *Hind*III site at nucleotide 4,990 to an *Eco*RI site created by *Bal*31 nuclease digestion of HTLV-I proviral DNA and insertion of a synthetic oligonucleotide at position ~8,890) was ligated into pSV2-neo doubly digested with *Hind*III and *Eco*RI. The neomycin resistance and SV40 termination-polyadenylation sequences of pSV2-neo were deleted, and transcription of the HTLV-I insert is terminated in the 3' LTR.

Fig. 2 CAT activity measured in COS cells transfected with HTLV constructions. **a**, High levels of CAT are expressed from a modified construct of the SV40-based vector pSV-CAT²⁶ on transfection into COS cells. The structure of the HTLV-I LTR-CAT construction (LTR-I-CAT) and HTLV-II LTR-CAT (LTR-II-CAT) is as described elsewhere^{15,20}. Transfection with LTR-I-CAT or LTR-II-CAT alone produces a very low background CAT activity. Co-transfection with SV-HTLV produces CAT activity approaching that obtained with pSV-CAT. Co-transfection with constructions pH6-neo or cH6-H11 produces CAT activity not significantly higher than that obtained with LTR-CAT alone. Relative conversion of chloramphenicol into acetylated forms (expressed as a percentage of SV-CAT control) from at least three experiments was as follows: LTR-I-CAT, <1%; LTR-II-CAT, <1%; SV-HTLV+LTR-I-CAT, 16%; SV-HTLV+LTR-II-CAT, 9%; SV-3.9+LTR-I-CAT, 10%; SV-3.9+LTR-II-CAT, <1%. Less than threefold variation in levels of CAT activity observed between assays were not considered significant. **b**, *Hind*III digestion of SV-HTLV cleaves the construct at the ends of the HTLV-II insert. Co-transfection of LTR-CAT with *Hind*III-digested SV-HTLV abolishes (<1% SV-CAT control) the CAT activity seen in co-transfections with the native DNA, indicating that both the SV40 and HTLV-II sequences present in the construction are required to achieve *trans*-activation of LTR-CAT. **c**, Transfection of LTR-I-CAT (5 μ g) with 3.0 μ g, 0.6 μ g and 0.12 μ g of SV-HTLV (lanes A-C); LTR-II-CAT (5 μ g) with 3.0 μ g, 0.6 μ g and 0.12 μ g (lanes D-F) of SV-HTLV. pSV2-neo DNA was used as carrier to bring the total amount of DNA to 10 μ g in each case. Transfection with 0 μ g of SV-HTLV induces only a background level of CAT activity (**a**). Dose response to the HTLV-II vector SV-HTLV is similar for both LTR-I-CAT and LTR-II-CAT (see text). **Methods**. 2×10^6 COS cells were seeded on 100-mm plates and transfected after 24 h with 10 μ g of DNA, using the calcium phosphate co-precipitation technique³⁷. Cells were collected 40-48 h after transfection and CAT activity determined by TLC. The amount of CAT activity is indicated by conversion of ¹⁴C-radiolabelled chloramphenicol (left) into acetylated forms (right). Results were quantified by cutting out bands and determining the amount of radiolabel in each by liquid scintillation counting.

only in co-transfections with the SV-HTLV and SV-3.9 constructs, and not in transfections with the other HTLV constructs. This is due to more efficient transcription of HTLV genes from the SV40 promoter than by the HTLV-II LTR (ref. 20 and see Fig. 2a). The HTLV-II construction SV-HTLV is capable of activating transcription from both the LTR-I-CAT and LTR-II-CAT constructs, but the HTLV-I construct SV-3.9 efficiently activates only LTR-I-CAT. This is consistent with the observations of other investigators who found that the LTR of HTLV-I is activated in HTLV-II-infected cells but that the HTLV-II LTR is only weakly active in HTLV-I-infected cells¹⁶. *Trans*-activation is abolished in co-transfections with *Hind*III-digested SV-HTLV, in which the HTLV-II insert is removed from the SV40 promoter/termination sequences in the vector (Fig. 2b). Figure 2c shows the dose-response obtained by co-transfection of COS cells with LTR-CAT and decreasing amounts of the SV-HTLV construction. Efficient expression of the CAT gene by the LTR is clearly dependent on the presence of the intact SV-HTLV construct in the transfection; dilution or restriction endonuclease digestion of SV-HTLV decreases or abolishes the activation of LTR function. Therefore, transcriptional activation of the LTR is dependent on expression of HTLV functions which are supplied in these co-transfection experiments by SV-HTLV. Similar results were obtained in co-transfections of other cell lines, including HeLa cells and lymphoid cells such as Epstein-Barr virus-transformed B cells (data not shown). We will refer

to this *trans*-acting transcriptional activation of LTR functions as the *trans*-regulatory function of HTLV.

To determine which of the HTLV genes was responsible for activation of the LTR, we introduced mutations into the SV-HTLV construction described above. These mutants were used in the COS cell co-transfection system together with LTR-CAT (see Fig. 3). The HTLV χ gene is encoded by a 2.1-kb messenger RNA derived by the splicing of two introns, the first of which contains the *gag* and *pol* genes and the other the major part of the *env* gene and the untranslated region of the genome²¹. The middle exon supplies four nucleotides which encode the NH₂-terminus of the χ protein. These four nucleotides are derived from the *env* gene methionine codon and one additional nucleotide which is spliced to the major χ open reading frame of the third exon. Only mutations which affect the expression of χ (SV-HTLV-Xho and SV-HTLV-Cla) (see Fig. 3 legend for details of constructs) abolish transcriptional activation. Other mutations in the *gag*, *pol* and *env* genes (SV-HTLV-Sst, Xba, EXB) did not abolish the *trans*-regulatory function of the genome. Note that mutants bearing deletions in the 700-bp nontranslated region of the HTLV-II genome (SV-HTLV-ExB

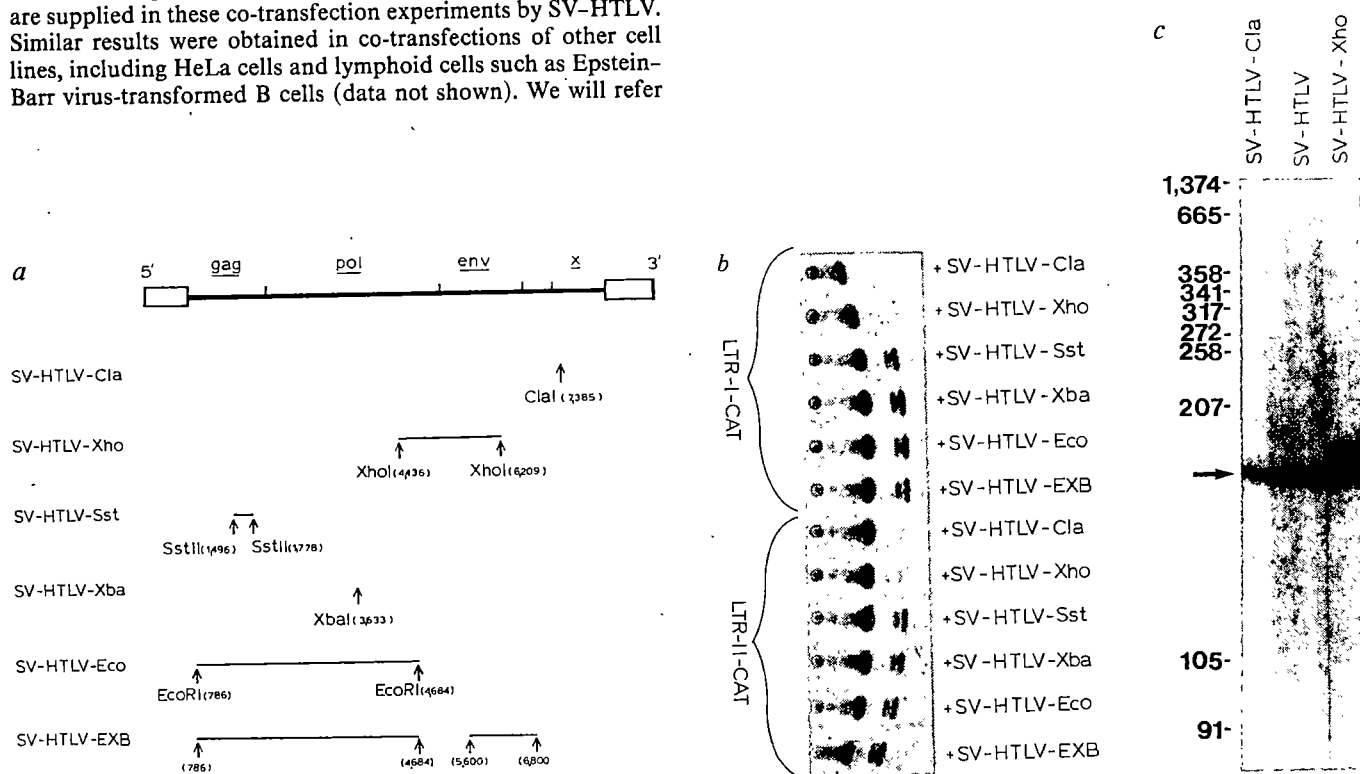

Fig. 3 a, Location of mutations introduced into SV-HTLV. The mutant SV-HTLV-Sst has a 309-bp deletion in *gag* p24 (position 1,469–1,778) and activates the LTR in co-transfection assays. SV-HTLV-Xba has a frameshift mutation in the *pol* gene, due to a 4-bp insertion at position 3,633. These four bases were introduced by treatment of *Xba*I-digested SV-HTLV with the large fragment of *E. coli* DNA polymerase I and recircularization with DNA ligase. Although this mutant would be expected to produce a truncated *pol* gene product, this does not affect *trans*-regulation of the LTR. SV-HTLV-Eco has a 3,898-bp deletion (788–4,686), created by removal of an *Eco*RI fragment, which deletes the whole of the *gag* region and most of the *pol* gene but leaves intact *env* and χ gene coding sequences²¹. SV-HTLV-EXB was derived from SV-HTLV-Eco by a *Bal*31 nuclease deletion at a *Xho*I site at position 6,209 in the *env* gene of SV-HTLV-Eco. The *Bal*31-induced deletion in this mutant is ~1.2 kb long and extends from the *env* glycoprotein gp52 at the 5' end into the nontranslated region upstream of the χ open reading frame (position ~5,700–6,900). This mutant has deletions of *gag*, *pol* and *env* which total 5.1 kb of the 8.2-kb HTLV-II insert in SV-HTLV and is still capable of *trans*-activating both LTR-CAT constructions efficiently. SV-HTLV-Xho contains a 1,773-bp deletion (4,436–6,209) in the HTLV insert which deletes the 3' portion of the *pol* gene, *env* glycoprotein gp52 and the 5' portion of the transmembrane protein p20. Although this mutant retains the major coding region of the χ gene in the third exon, it is not expected to produce a functional χ gene product because of the deletion of the middle exon containing the initiation codon required for χ gene expression²¹. Co-transfections with this mutant do not produce increased CAT activity over that seen with LTR-CAT alone. SV-HTLV-Cla has a frameshift mutation in the χ gene, due to a 2-bp insertion into *Cla*I-digested SV-HTLV at position 7,385. This change is expected to produce an altered χ protein. The native p37^{HTLV-II} protein (relative molecular mass 40,000) comprises a total of 339 amino acids, 337 of which are coded between nucleotide positions 7,190 and 8,202 in HTLV-II. The altered predicted protein from SV-HTLV-Cla comprises 158 amino acids, that is, 67 from the native protein at the N-terminus and 91 amino acids from a different reading frame at the C-terminus (position 7,660). This predicted protein, unlike the native protein produced by SV-HTLV, cannot activate LTR-CAT. b, CAT activity in COS cells co-transfected with LTR-CAT and SV-HTLV mutants. Cells were transfected and CAT activity measured as described for Fig. 2. Lanes 1–6 received 5 μ g of LTR-I-CAT; lanes 7–12, 5 μ g of LTR-II-CAT. 5 μ g of DNA from each mutant were used as indicated on the figure. Relative conversion of chloramphenicol into acetylated forms (as a percentage of SV-CAT control) from at least three experiments was as follows: LTR-I-CAT+SV-HTLV-Cla, <1; +SV-HTLV-Xho, <1; +SV-HTLV-Sst, 20; +SV-HTLV-Xba, 21; +SV-HTLV-Eco, 10; +SV-HTLV-EXB, 15; LTR-II-CAT+SV-HTLV-Cla, <1; +SV-HTLV-Xho, <1; +SV-HTLV-Sst, 17; +SV-HTLV-Xba, 22; +SV-HTLV-Eco, 11; +SV-HTLV-EXB, 13. Less than threefold variation in levels of CAT activity observed between assays was not considered significant. c, S₁ nuclease analysis of 50 μ g of cytoplasmic RNA from transfected COS cells. S₁ analysis of χ mRNA was performed using a *Hha*I/*Cla*I ³²P-5' end-labelled probe (nucleotide positions 6,957–7,387) for the HTLV-II χ splice-acceptor site (position 7,214). Processed χ mRNA is indicated by the presence of a protected DNA fragment of 174 nucleotides, indicated by an arrow (see ref. 38).

and others; data not shown) between *env* and χ also retained *trans*-regulatory function, indicating that this region is not involved in expression of *trans*-regulatory functions as assayed by co-transfection.

S₁ nuclease analysis was used to examine the production of χ RNA by the SV-HTLV mutants. An S₁ nuclease probe specific for processed χ mRNA demonstrated that comparable levels of mRNA were produced by each of the constructions including the χ gene mutant SV-HTLV-Cla, indicating that the defect in SV-HTLV-Cla is in the translation of a functional χ gene product, not in χ mRNA levels (Fig. 3c). The apparently aberrant splicing observed with SV-HTLV-Xho may be due to loss of the second exon in the normal χ mRNA. These results demonstrate that only mutations which interfere with correct processing (SV-HTLV-Xho) or translation (SV-HTLV-Cla) of χ gene mRNA prevent *trans*-regulation of LTR-CAT. Other mutations which do not prevent expression of χ , including those that abolish all other viral genes, *gag*, *pol* and *env* (SV-HTLV-EXB), do not affect LTR *trans*-regulation, indicating that expression of the χ protein appears to be the single factor mediating *trans*-regulation and that no other virus gene is required.

HTLV differs from other retroviruses by the presence of a distinct locus, the χ gene, which is responsible for transcriptional regulation. A transcriptional activator locus has also recently been identified in a different reading frame of the *gag* gene of Rous sarcoma virus²³. There appears to be no comparable locus in HTLV, as mutants which completely lack the *gag* gene still activate the LTR efficiently. Unlike the χ gene of HTLV¹⁵, it is not known whether the *gag* activator locus is essential for replication of Rous sarcoma virus. These studies show directly that the requirement of the χ gene for viral replication is due to the transcriptional regulatory functions of the χ gene on the LTR. The presence of the χ gene may provide additional advantages for transcriptional regulation of HTLV expression in the host cell. The HTLV-II construct SV-HTLV can activate both the HTLV-I LTR and HTLV-II LTR, indicating a similar function for the χ proteins of both viruses, consistent with the sequence homology between the HTLV χ proteins^{13,14} and similar biological properties of HTLV-I and -II χ proteins⁵⁻⁸. The failure of the HTLV-I construct SV-3:9 to activate transcription from LTR-II-CAT is probably due to differences in the LTRs of HTLV-I and -II.

The function of the χ gene in HTLV transcription and replica-

tion must have a major influence on cellular transformation by, and on the pathogenicity of, HTLV. The kinetics of HTLV replication following infection may be related to the level of χ gene expression. Following integration into the genome of the host cell, low levels of χ mRNA are transcribed. Production of small amounts of the χ protein would stimulate LTR function, in turn producing higher levels of χ protein, and so on. This hypothesis is consistent with the slow kinetics observed in HTLV infection of cells (J.D.R., unpublished) and contrasts with typical retrovirus infections, where stable levels of RNA expression merely require passage of the infected cell through the S phase of the cell cycle^{24,25}.

Functional analogies exist between the HTLV χ gene and transcriptional regulatory genes of some DNA viruses. The best studied example of such a gene is the *E1a* gene of adenoviruses. Like χ , the product of *E1a* regulates adenovirus transcription by stimulating the transcription of other adenovirus genes^{26,27}. Since adenoviruses are capable of transforming certain cell types and *E1a* itself is required to transform cells^{28,29}, it seems likely that the HTLV χ gene may also be involved in cellular transformation. Structural and functional similarities have recently been found between the cellular oncogenes *myc*, *myb* and adenovirus *E1a* proteins³⁰, and we have recently shown that there are striking functional similarities between χ and *E1a*³¹. It is becoming apparent that the χ gene shares functional similarities with other transcriptional regulatory proteins, and like them, may also be involved in oncogenesis, possibly by causing aberrant transcriptional regulation in cells in which they are expressed (see refs 32, 33). Studies on the similarities between χ and other proteins known to be capable of cellular transformation will help to determine the role of the χ protein itself and the influence of altered transcriptional regulation as a mechanism for carcinogenesis.

We thank J. Fujii, C. Nishikubo and S. Quan for technical assistance, R. Gaynor and D. Golde for helpful discussions, and W. Aft for preparation of the manuscript. This work was supported by NCI grants CA30388, CA32737, CA38597, CA09297 and CA16042, grants PF-2182 and JFRA-99 from the American Cancer Society, grants from the California Institute for Cancer Research and California University-wide Task Force on AIDS. W.W. is a Bank of America-Giannini Fellow.

Note added in proof: Since the submission of this manuscript, two additional reports have confirmed the role of the χ gene in transcriptional activation of the HTLV LTR^{39,40}.

Dissociation of transforming and *trans*-activation functions for bovine papillomavirus type 1

Yu-Chung Yang, Barbara A. Spalholz,
Michael S. Rabson & Peter M. Howley

Laboratory of Tumor Virus Biology, National Cancer Institute,
Bethesda, Maryland 20892, USA

It has been shown that genetic information encoded by the 3' open reading frames (ORFs), E2, E3, E4 and E5, of bovine papillomavirus type 1 (BPV-1), is sufficient to induce cellular transformation of certain mouse cells¹⁻⁵. The product of the E2 ORF has further been shown to be responsible for the *trans*-activation of a transcriptional regulatory element located in the noncoding region (NCR) of the BPV-1 genome⁶. To examine whether or not the E2 *trans*-activation function is encoded by the same gene that encodes the 3' ORF viral transformation function, we have now analysed the expression of the *trans*-activation function in series of mouse C127 cells transformed by BPV-1 deletion mutants. In addition, using mutated complementary DNA clones generated by the insertion of a premature translational termination linker into different sites of a BPV-1 cDNA clone containing the 3' ORFs intact, we demonstrate that transformation and transcriptional *trans*-activation functions can be dissociated and that they map respectively to the E5 and E2 ORFs.

BPV-1 or its cloned full-length DNA can transform certain rodent cells *in vitro* and the viral DNA persists as an extra-chromosomal multi-copy plasmid in these transformed cells⁷. The genetic organization of BPV-1 has been established from the analysis of the DNA sequence⁸ and the viral RNA transcripts (Fig. 1)^{3,9-13}. Mutagenesis studies have identified several regions of the BPV-1 genome which influence the expression of the viral transformation functions. Mutations affecting the E2 ORF result in a reduced ability to transform mouse cells, suggesting a role for the putative E2 viral gene product in the transformation process^{2,4,5}. Mutations affecting the E5 ORF also have a marked effect on transformation efficiency^{5,14-16}. The E6 ORF encodes

an independent transforming protein^{3,21} and its function is critical for expression of the fully transformed phenotype². A transcriptional enhancer, which is activated in *trans* by the putative E2 gene product, has been mapped within the 1-kilobase (kb) NCR of the BPV-1 genome⁶.

To examine whether or not the *trans*-activation function of the E2 gene product is linked to the BPV-1 transforming functions of the 3' ORFs, cell lines transformed by different BPV-1 deletion mutants (shown in Fig. 1) were tested for their ability to activate the NCR enhancer. Table 1 lists the cell lines assayed. C127 cells are not transformed and do not contain BPV-1 DNA sequences, and as such serve as a negative control. NS142-6 cells are C127 cells transformed by a plasmid containing the entire BPV-1 genome cloned into the pML2d vector and provide the factor capable of *trans*-activating the NCR enhancer present in p407-1 (ref. 6). The NS620-7 and NS236-12 cell lines have been transformed with BPV-1 deletion mutants that affect the 5' ORFs (E5, E7, E1 and E8). As previously reported, both of these cell lines can provide the *trans*-acting factor to activate p407-1, confirming that the 3' ORFs encode the diffusible *trans*-acting factor⁶. The NS327-25, NS448-5 and NS618-5 cell lines have each been transformed by BPV-1 mutants containing deletions extending various distances upstream from the *Bcl*I site at base 3,838. The p327-25 mutant has a 101-base deletion which affects the carboxy terminus of E2 as well as the 5' terminus of the E5 ORF, upstream of the first E5 AUG methionine codon. This deletion mutant has a transforming activity similar to that of full-length BPV-1 DNA. The mutants p448-5 and p618-5 contain larger deletions which affect the E3 and E4 ORFs as well as the E2 and E5 ORFs. These mutants transform at a level approximately 10% and 1%, respectively, of that of wild-type BPV-1 DNA or of p327-25 DNA². Consistent with previous studies mapping the *trans*-activating factor to the E2 ORF, none of these mutants were able to activate the NCR enhancer in p407-1, despite their varied transformation capability⁶. These data suggest that BPV-1-mediated transformation and a transcriptional activation imparted by the E2 ORF gene product can be unlinked. It is of interest that the activity of the BPV-1 NCR chloramphenicol acetyl transferase (CAT) plasmid p407-1 is higher in those lines transformed by BPV-1 plasmids mutated in the E1 ORF than in the line transformed by the BPV-1

Fig. 1 Structure of the BPV-1 DNA deletion mutants used in transforming mouse C127 cells assessed for providing the NCR/CAT *trans*-acting factor. The recombinant plasmid and deletion are indicated on the left. Each of these plasmids is cloned in pML2d at the *Bam*HI site as indicated by an open triangle. The retained sequences (open box) are covalently linked at the sites indicated and in the figure are separated by the deleted sequences (...). *Xho*I linkers are indicated by a diamond. The ORFs for the BPV-1 genome are indicated at the top of the figure, as are the bases defining the beginning and the ends of each of the ORFs. The E6, E7, E1 and E8 ORFs are referred to in the text as the 5' ORFs because of their location, and the E2, E3, E4 and E5 ORFs are referred to as the 3' ORFs. No significantly large ORFs are located between the *Hind*III site (base 6,959) and the *Hpa*I site (base 7,945/1) and this segment is referred to as the noncoding region (NCR). The construction of each of these deletion mutants has been described previously². The ORFs affected by the deletion mutants are listed on the right. These constructions are presented relative to the map of BPV-1 ORFs and the linear genome. All of the detectable polyadenylated mRNA species are transcribed from a single strand and all ORFs are located on the same strand.

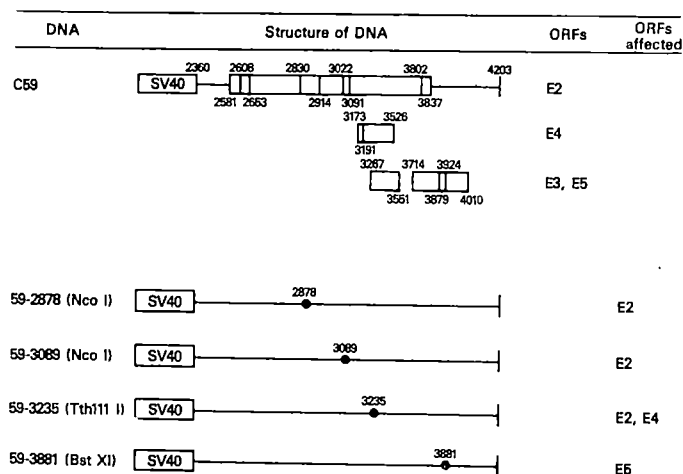

Fig. 2 Structure of the C59 cDNA clone and derived mutants. The structure of this clone is shown at the top of the figure with the SV40 early promoter and late introns located 5' to the BPV-1 ORFs³. The E2, E3, E4 and E5 ORFs are contained intact in the C59 clone. Each of these ORFs is indicated by an open box. Vertical lines in the open boxes represent the AUG codons which could potentially be used to initiate translation. Numbers adjacent to the ORFs represent the 5' and 3' boundaries of the ORFs as well as the location of the AUG codons. The mutants containing the linker fragment with the premature termination codon are indicated below with the position of the in-frame termination codon indicated. The sequence of the synthetic premature translation termination linker which also contains a restriction endonuclease site for *Hpa*I is

TAAGTTAACTAG
ATTCAGTTCAT

ORFs which would be affected by the insertion of the premature termination codon linker are listed on the right.

full-length genome. Whether this is simply due to experimental cell line variability or to a negative transcriptional regulatory effect mediated by the product(s) of one or more of the 5' ORFs is under investigation.

To separate further the *trans*-activation and transformation functions within the BPV-1 genome, we have introduced a premature translational termination codon linker at various positions into the BPV-1 cDNA clone, C59 (Fig. 2)³. This DNA can transform mouse C127 cells and *trans*-activate the BPV-1 NCR enhancer element^{3,6}. The C59 clone can be predicted to direct the synthesis of the putative E2 protein (relative molecular mass 48,000) with initiation and termination codons at nucleotides 2,608–2,610 and 3,838–3,840, respectively. This cDNA clone, however, also contains the E3, E4 and E5 ORFs intact. By inserting a synthetic linker containing translational stop codons in each of the three reading frames into the different ORFs, we were able to assess the role of each ORF in transformation and *trans*-activation. The structure of each of the resultant linker insertion mutants was verified by DNA sequence analysis and each was shown to contain a single linker insertion (data not shown). Each of the resultant mutants was assayed for its ability to transform mouse C127 cells and to *trans*-activate the NCR transcriptional regulatory element in p407-1 using an acute assay on monkey CV-1 cells (Table 2). The mutants C59-2878

and C59-3089, which affect only the E2 ORF, were unable to provide the diffusible factor for *trans*-activation of the BPV-1/ncr/CAT in the CAT assay; however, they retained the full transforming function on mouse C127 cells. The mutation in 59-3235, located at the *Tth*III site, affects the E2 and E4 ORFs and resulted in the loss of the *trans*-activation function but did not affect the transforming function. Only in 59-3881, in which the premature termination codon was inserted at the *Bst*XI site at base 3,881, was the transformation function abolished. The NCR *trans*-activation function, however, remained intact. The termination linker in 59-3881 is located in the E5 ORF downstream from the first AUG at base 3,879; the E2, E3 and E4 ORFs are intact in this mutant. The retention of *trans*-activation function in 59-3881 indicates that this mutation does not affect the stability of the E2 messenger RNA and strongly suggests that the E5 ORF has a critical role in transformation.

The role of the E5 ORF in transformation has been implicated in other studies using mutants possessing deletions or insertions in the full-length BPV-1 genome^{5,14,16} and in a subgenomic fragment of the BPV-1 genome promoted from a retrovirus long terminal repeat¹⁵. However, these initial studies have not revealed whether the mutations at the *Bst*XI site were altering transformation by affecting critical coding sequences or through regulatory sequences required in *cis*. As yet, no viral RNAs have been found splicing into the E5 ORF and no obvious splice acceptor sequence is located in the vicinity. The fact that the non-transforming mutant 59-3881 provides the *trans*-activation function argues that the mutation at the *Bst*XI site does not affect the stability or translatability of the viral RNA. These results, therefore, provide compelling evidence that the E5 ORF is a coding domain for a critical transforming protein. The E5

Table 1 Chloramphenicol acetyltransferase expression from CAT recombinant plasmids in C127 cells transformed by BPV-1 deletion mutants

Cell line	BPV-1 deletion in transforming DNA	ORFs affected	CAT activity		
			pA ₁₀ CAT	pSV2CAT	p407-1
C127	—	—	0.7	37.5	1.6
NS142-6 1	None	None	0.4	36.5	6.7
NS620-7 B	2,113–2,405	E1	0.6	26.7	17.5
NS236-12 B	1–2,405	E6, E7, E8, E1	0.1	11.2	12.7
NS236-12 C	1–2,405	E6, E7, E8, E1	0.2	42.2	29.2
NS327-25 A	3,737–3,838	E2, E5	0.6	33.7	1.4
NS448-5 A	3,456–3,838	E2, E3, E4, E5	1.1	26.2	3.1
NS618-5 B	2,775–3,838	E3, E3, E4, E5	1.7	29.7	3.3

Each of the cell lines was selected by its transformed phenotype. In each of the cell lines transformed by a BPV-1 deletion mutant, the BPV-1 DNA was in an integrated form². Each cell line was independently transfected with the plasmids pA₁₀CAT²⁶, pSV2CAT²⁷ and p407-1⁶ and assayed 48 h post-transfection for CAT activity. The pSV2CAT plasmid contains the *cat* gene in a modified eukaryotic transcriptional cassette promoted by the full simian virus 40 (SV40) early region promoter including the repeated 72-base-pair functional enhancer²⁷. The pA₁₀CAT plasmid was derived from pSV2CAT and lacks the functional enhancer but still contains the early promoter²⁶. The p407-1 plasmid was derived from pA₁₀CAT by the insertion of the BPV-1 *Hind*III/*Hpa*I NCR fragment in the *Bgl*II site of pA₁₀CAT, 5' to the SV40 early promoter in the transcriptional sense orientation⁶. CAT activity is measured as the % of chloramphenicol which is acetylated by the cellular extract in 30 min at 37 °C. The cellular extract in each assay was normalized for protein content before incubation. Deletions are given in terms of the nucleotide number of the BPV-1 genome.

Table 2 Transformation and *trans*-activation by cDNA clones containing termination codons

Clone no.	Transformation (foci per plate)	CAT activity		
		pA ₁₀ CAT	pSV2CAT	p407-1
C59	26, 40	0.4	61.0	61.0
C59-2878*	21, 31	0.3	55.0	1.7
C59-3089	23, 50	ND	ND	0.3
C59-3235	12, 42	0.3	70.8	1.2
C59-3881	0, 0	0.2	61.2	62.9
Salmon sperm DNA	0, 0	0.3	10.3	1.2

Transformation of C127 cells was carried out with 5 µg of the indicated cDNA clone using salmon sperm DNA as carrier as previously described³. CAT activity is measured as the % of chloramphenicol which is acetylated by the cellular extract in 30 min at 37 °C. CV-1 cells were transfected with each of the above cDNA clones listed and with the plasmids pA₁₀CAT²⁶, pSV2CAT²⁷ and p407-1⁶. Cell extracts were prepared 48 h post-transfection. ND, not determined.

* This clone has been referred to previously as C59N-9 (ref. 6).

ORF would be predicted to encode a 44-amino-acid hydrophobic protein.

The role of the product of the E5 ORF in the pathogenesis of a fibropapilloma is not known, although it may be involved in the proliferation of the dermal fibroblasts characteristic of a fibropapilloma. ORFs analogous to E5 in BPV-1 have been identified in other papillomavirus genomes that have been sequenced. The sequence of E5 ORFs of HPV-1a (ref. 17) and Shope papillomavirus¹⁸, which induce purely epithelial lesions, however, are not homologous to the E5 ORF of BPV-1. HPV-6b is associated with condyloma acuminata in humans and contains an E5a ORF which shares only slight homology with the E5 ORF of BPV-1¹⁹. There is, however, a small ORF in the corresponding region of the deer papillomavirus genome²⁰ and of the BPV-2 genome (W. D. Lancaster, personal communication) which has the potential to encode a peptide strikingly similar in size and amino-acid composition to the BPV-1 E5 ORF. Like BPV-1, the deer papillomavirus and BPV-2 each induces fibropapillomas in their natural host and fibroblastic tumours in hamsters, and readily transforms rodent cells in culture.

The mechanism by which the putative E2 gene product can *trans*-activate the NCR transcriptional regulatory element and its interaction with other viral or cellular genes during the transformation process remains unknown. The dissociation of the *trans*-activation and transformation functions of the 3' ORFs demonstrated here suggests that the E2 gene product may function indirectly through the activation of the NCR transcriptional regulatory element. The activation of the NCR enhancer by the E2 gene product could lead to increased transcription from the upstream promoter and expression of the 5' ORFs including E6, E6/E7 and E1, which have been shown to affect transformation and plasmid maintenance²⁻⁴. However, we have not ruled out the possibility that the E2 ORF gene product may have a direct effect on transformation. Our assay for transformation has been done using the mouse C127 cell line, which is an established cell line. It is possible that the E2 ORF has a direct transformation function but one that must be assayed in a different cell system. Other viral and cellular genes whose products have *trans*-activation properties, including the adenovirus E1a gene²² and the *c-myc* gene²³, have been shown to interact with other transforming genes in transforming primary cells^{24,25}. It is possible that *trans*-activation is only one of several pleiotropic functions of the E2 gene product.

We thank Nan Freas for the preparation of this manuscript. Forensic application of DNA 'fingerprints'

Peter Gill*, Alec J. Jeffreys† & David J. Werrett*

* Central Research Establishment, Home Office Forensic Science Service, Aldermaston, Reading, Berkshire RG7 4PN, UK

† Department of Genetics, University of Leicester, University Road, Leicester LE1 7RH, UK

Many highly polymorphic minisatellite loci can be detected simultaneously in the human genome by hybridization to probes consisting of tandem repeats of the 'core' sequence¹. The resulting DNA fingerprints produced by Southern blot hybridization are comprised of multiple hypervariable DNA fragments, show somatic and germline stability and are completely specific to an individual^{2,3}. We now show that this technique can be used for forensic purposes; DNA of high relative molecular mass (M_r) can be isolated from 4-yr-old bloodstains and semen stains made on cotton cloth and digested to produce DNA fingerprints suitable for individual identification. Further, sperm nuclei can be separated from vaginal cellular debris, obtained from semen-contaminated vaginal swabs, enabling positive identification of the male donor/suspect. It is envisaged that DNA fingerprinting will revolutionize forensic biology particularly with regard to the identification of rape suspects.

Biological samples for forensic analysis consist mainly of bloodstains or semen stains on cloth or other surfaces (often several days or even weeks old), vaginal swabs taken after an alleged rape, and sometimes hair roots^{4,5}. Current methods for typing blood and semen stains are reviewed by Divall⁶ and Sensabaugh⁷. Typically, a battery of polymorphic protein and blood group marker systems are used (the Metropolitan Police Forensic Science Laboratory, London, currently use ABO, adenylate deaminase (ADA), adenylate kinase (AK), carbonic anhydrase (CA-II), erythrocyte acid phosphatase (EAP), esterase D (EsD), glyoxalase I (GLO), haemoglobin (Hb), peptidase A (Pep A), phosphoglucomutase (PGM₁), Gm, Lewis and rhesus (Rh) for blood analysis). Detection of PGM₁, EAP, ADA and Rh is difficult after 26 weeks^{7,8}; EsD and CAII cannot be reliably detected after 1 month⁷. In contrast, only five systems are at present in common use for identifying genetic markers in semen (ABO, PGM, GLO, Pep A and Lewis) and all must be used with considerable caution because semen samples analysed are often contaminated with vaginal fluid which itself has enzyme and blood group activity. Semen contains proteolytic enzymes which further reduce the amounts of proteins recovered⁹. Furthermore, bacterial activity may be responsible for producing erroneous results, particularly in the identification of ABO blood groups^{10,11}.

DNA fingerprints can only be obtained from high- M_r undegraded DNA. Previous attempts to isolate DNA from dead or aged material have been reported from 140-yr-old quagga muscle¹² and 2,400-yr-old mummies¹³. In both cases only low- M_r DNA was obtained, and it was therefore necessary to establish whether intact DNA could be isolated from samples which may be typically encountered in forensic laboratories.

Multiple samples were prepared from 11 different donors. Bloodstains and semen stains were prepared by aliquoting fresh material onto clean cloth which was air-dried before storage at ambient temperature and humidity. Hair roots were analysed

Fig. 1 Isolation of high relative molecular mass DNA from dried bloodstains, semen stains and hair roots. Lane 1, fresh blood (60 μ l); lane 2, 6-week-old bloodstain (60 μ l equivalent); lane 3, 20-month-old bloodstain (60 μ l equivalent); lane 4, fresh semen (20 μ l); lane 5, 5-week-old semen stain (20 μ l equivalent); lane 6, degraded sample of 5-yr-old semen stain (40 μ l equivalent); lane 7, fresh hair roots ($\times 15$) (RNA is also clearly visible from hair roots); lane 8, fresh blood (60 μ l); lanes 9–14, control human placental DNA, 0.1 μ g, 0.2 μ g, 0.4 μ g, 0.8 μ g, 1.6 μ g, 3.2 μ g respectively.

Methods. Whole blood, semen, hair roots, bloodstains and semen stains were incubated overnight in 1.5-ml microcentrifuge tubes at 37 °C in 0.01 M Tris-HCl, 0.01 M EDTA, 0.1 M NaCl (pH 8.0) containing 2% SDS, 20 μ g ml⁻¹ proteinase K and 0.039 M DTT. DNA was purified by two phenol/chloroform extractions and precipitated by the addition of 0.1 volume of 2 M sodium acetate and 2.5 volumes of absolute ethanol. The DNA was pelleted by centrifugation at 15,000g for 5 min, washed with 70% ethanol and repelleted. If a residue remained (suggesting contamination by low- M_r compounds), the sample was dissolved in 20 μ l of sterile distilled water and passed down a small spun column (200 μ l Sephadex G-50 contained in a 0.75-ml microcentrifuge tube)¹⁵. Samples were electrophoresed on a 10-cm 0.5% agarose gel at 80 V for 2 h, and DNA was visualized by staining with ethidium bromide.

Fig. 2 Somatic stability and ageing studies. Individual *a*: lane 1, degraded sample from 5-yr-old semen stain (40 μ l equivalent); lane 2, 4-week-old semen stain (40 μ l equivalent); lane 3, fresh semen (40 μ l); lane 4, whole blood (60 μ l); lane 5, 4-week-old bloodstain (60 μ l equivalent); lane 6, 2-yr-old bloodstain; lane 7, fresh hair roots ($\times 15$). Individual *b* (showing differences between DNA fingerprints of *a* and an unrelated individual on the same Southern blot): lane 8, fresh blood (60 μ l). Individual *c*: lane 1, fresh semen (20 μ l); lane 2, 11-week-old semen stain (20 μ l equivalent). Individual *d*: lane 1, fresh semen (20 μ l); lane 2, 11-week-old semen stain (20 μ l equivalent); lane 3, hair roots ($\times 13$). Individual *e*: lane 1, fresh blood (60 μ l) (the largest band is high- M_r DNA at the electrophoretic exclusion point); lane 2, 1-day-old bloodstain (80 μ l equivalent); lane 3, 30-month-old bloodstain (80 μ l equivalent); lane 4, 4-year-old bloodstain (80 μ l equivalent).

Methods. Samples were prepared as described for Fig. 1. DNA was digested with *Hinf*I (20 units), in the presence of 4 mM spermidine trichloride, for 2 h at 37 °C. Samples were phenol extracted and ethanol precipitated before electrophoresis through a 20-cm long 0.6% agarose gel at 35 V for 20 h. DNA was denatured *in situ*, transferred to a Schleicher and Schull membrane filter (BA85) and filter-hybridized to ³²P-labelled single-stranded minisatellite probe 33.15 as described elsewhere^{1,2}. Autoradiography was carried out at -80 °C, with an intensifying screen, for 7 days.

fresh. Semen-free and semen-contaminated vaginal swabs (taken at a known period of time after intercourse) were also obtained together with blood samples from both the female and the male. All swabs were stored at -20 °C before use. DNA was extracted from whole blood, whole semen, vaginal fluid, hair roots, bloodstains and semen stains by overnight incubation in an SDS/proteinase K/dithiothreitol (DTT) mixture. Because preliminary experiments showed that semen-contaminated vaginal swabs contained large amounts of DNA from the female, tending to obscure many of the bands from the sperm, female cells were preferentially lysed by preliminary incubation in an SDS/proteinase K mixture. Sperm nuclei are impervious to this treatment because they are ramified with cross-linked thiol-rich proteins¹⁴ and can therefore be separated from the female component by centrifugation. Sperm nuclei were subsequently lysed by treatment with an SDS/proteinase K/DTT mixture. Electrophoresis of samples on 0.5% agarose gels showed that high- M_r DNA could be isolated from bloodstains and semen stains that were at least 2 years old and from fresh hair roots (Fig. 1). However, no DNA could be isolated from hair shafts.

DNA fingerprints obtained from all bloodstains, semen stains and hair roots were shown to be specific to individuals when compared with whole blood and semen samples (Fig. 2). Approximately 5 μ l of semen or equivalent semen stain and 60 μ l of blood or equivalent bloodstain were required. Some samples analysed were partial digests (Fig. 2e) but these also showed patterns consistent with those of a particular individual. DNA fingerprints were obtained from bloodstains up to 4 yr old (Fig. 2e). High- M_r DNA from a 5-yr-old semen stain (Fig. 1, lane 6; Fig. 2a, lane 1) and a 3-yr-old blood stain had degraded so that no pattern was visualized. After using the differential lysis technique only sperm DNA was isolated from a vaginal swab taken 6.5 h after intercourse (Fig. 3, lane 1).

These preliminary results demonstrate that DNA fingerprints are capable of changing completely the emphasis of blood-grouping in forensic science. Using eight polymorphic protein systems together, Sensabaugh⁷ quoted a probability of 0.014 for individual specificity. In practice, the degree of characterization is often much lower, particularly when semen is grouped. This leaves a large degree of uncertainty. In contrast, the condition

Fig. 3 DNA fingerprint from two vaginal swabs taken 6.5 h after intercourse (lane 1). The pattern is the same as that obtained from the male donor's blood (lane 2). The female's DNA fingerprint (from blood) is shown in lane 3.

Methods. Vaginal cells from semen-contaminated swabs were preferentially lysed by a preliminary incubation in the absence of DTT for 30 min using the lysis mixture described in Fig. 1 legend. Sperm nuclei were pelleted by centrifugation at 15,000g for 5 min, washed once, repelleted and lysed with the full SDS/proteinase K/DTT mixture. DNA was isolated as described in Fig. 1 legend and DNA fingerprints prepared (Fig. 2 legend).

of non-association has been absolute using traditional blood-grouping tests, that is, if the phenotype does not match, a common origin is not possible. Using two DNA minisatellite probes (33.15 and 33.6)¹, the degree of association can approach certainty—thus the probability of chance association using probe 33.15 is $<3 \times 10^{-11}$, and if two probes are used (33.15 and 33.6) the probability is substantially reduced to $<5 \times 10^{-19}$ (ref. 2). In short, using this single method, it is now possible for the forensic scientist to be positive about blood-grouping tests, whereas in the past, it was only possible to be sure of negative associations.

A.J.J. is a Lister Institute Research Fellow and this work was supported in part by a MRC grant to A.J.J. The minisatellite probes are the subject of a Patent Application. Commercial enquiries should be addressed to the Lister Institute of Preventive Medicine, Royal National Orthopaedic Hospital, Brockley Hill, Stanmore, Middlesex HA7 4LP, UK.

* Laboratorium voor Genetika, Rijksuniversiteit Gent, Gent B-9000, Belgium

Light regulates many varied physiological and developmental phenomena during plant growth and differentiation, including the formation of a photosynthetically competent chloroplast from a proplastid¹. The expression of ribulose 1,5-bisphosphate carboxylase small subunit (*rbcS*) genes is regulated by light in a development- and tissue-specific manner^{2,3}. In some plant species, phytochrome has been demonstrated to mediate this response⁴⁻⁷, and photoregulation of *rbcS* expression occurs at least in part at the level of transcription^{8,9}. We have shown previously that a 5'-noncoding fragment (4-973 base pairs (bp) upstream of the messenger RNA cap site) of the pea *rbcS* *ss3.6* gene contains all of the nucleotide sequence information necessary to direct the photoregulated expression of a bacterial chloramphenicol acetyltransferase (*cat*) gene in tobacco¹⁰. Consistent with these findings, Morelli *et al.*¹¹ have shown by deletion analysis of a second *rbcS* gene promoter, that the sequences required for photoregulated expression of *rbcS* E9 reside within the 5'-noncoding region. They identified an upstream region of ~700 bp needed for maximum transcription but not light-dark regulation, and a region from -35 to -2 bp which included the TATA box and contained the necessary information for light responsiveness. We now demonstrate that regulatory sequences 5' distal to the *rbcS* *ss3.6* TATA box and transcriptional start site not only contain the information necessary for maximum expression, but also confer photoregulation. These upstream regulatory sequences function independently of orientation when fused to their homologous promoter or a heterologous promoter.

The expression of many animal viral and cellular genes is influenced by regulatory sequences, commonly referred to as enhancers¹²⁻¹⁸, which characteristically function independently of orientation at various distances from the TATA box and start site of transcription^{12,16-18}. Certain enhancers activate gene expression only in specific cell types¹⁶⁻¹⁸, or in response to physiological stimuli¹⁵. It has not previously been investigated whether the expression of some plant genes is also regulated by enhancers.

The nucleotide sequence requirement for photoregulated expression of the *rbcS* *ss3.6* gene¹⁹ was examined using the CAT expression system²⁰. We and others^{10,20-23} have demonstrated the ability of this system to compare promoter efficiency and have shown that for chimaeric genes such as those used here, in which the mRNAs are identical, CAT activity reflects the cellular *cat* mRNA levels¹⁰ and therefore the transcriptional activity directed by the targeted promoter. To overcome any bias due to different RNA processing or translation efficiencies, the various test promoter fusions were always compared with the wild-type promoter.

To define more accurately the sequences within the -973 to -4 *rbcS* *ss3.6* promoter which are necessary to direct photoregulated expression, a series of promoter deletion mutants was constructed and tested for their ability to direct photoregulated *cat* gene expression in transformed tobacco calli (Fig. 1). Three of the constructs contain 5' deletions with endpoints at 722, 357 and 92 bp upstream from the cap site and the fourth contains a 3' deletion lacking sequences -4 to -90 (including the TATA box).

Fig. 2 Chloramphenicol acetyltransferase activity in transformed tobacco calli expressing truncated *ss-cat* chimaeric genes. Chimaeric genes containing truncated *ss3.6* promoters were introduced into tobacco cells and transformed calli grown in light or darkness. The upper panel shows a representative autoradiograph of thin layer chromatographic separation of CAT assay reaction products; the lower panel presents a summary of the data derived from these assays. The plasmid designation for the various deletion mutants appears above each pair of lanes. Extracts from light- and dark-grown tissues are designated LT and DK, respectively. CAP, ^{14}C -chloramphenicol; 1-AcCAP, 1-acetylchloramphenicol; 3-AcCAP, 3-acetylchloramphenicol.

Methods. Plasmids containing truncated *ss-cat* chimaeric genes were mobilized into *Agrobacterium tumefaciens* harbouring either the wild-type Ti plasmid, pTiC58, or the attenuated plasmid, pLGV-3851 (ref. 30), and stable recombinants were used to infect *Nicotiana tabacum* var. SR1 cells¹⁰. Several weeks after inoculation, tumours were removed from the plantlets and axenic homogeneous cell lines of transformed calli selected by hormone-independent growth. Independently derived transformants were subcultured and maintained at 28 °C both in darkness on MS media³¹ containing 3% sucrose and in light (12-h dark/light cycle) on MS media containing 0.1% sucrose and 0.2 $\mu\text{g ml}^{-1}$ 6-benzylaminopurine. Southern hybridization analysis of total DNA from transformed calli was performed to confirm the presence and integrity of introduced chimaeric genes (data not shown). CAT activity was assayed in extracts from transformed calli as described previously¹⁰, except that the reaction mixtures were preincubated at 37 °C for 5 min before the addition of acetyl CoA and the final concentration of acetyl CoA in the reaction was adjusted to 0.3 mM. Reaction products were separated in silica gel plates²¹ and located by autoradiography. Individual reaction products were cut from the silica plate and the radioactivity present determined by liquid scintillation. The amount of ^{14}C -chloramphenicol and its 1- and 3-acetyl derivatives were determined and activity is expressed as % conversion of chloramphenicol into its acetyl derivatives by 100 mg of tissue extract in 30 min. Induction is the ratio of CAT activity in light- versus dark-grown callus as determined from the per cent conversion. To calculate relative activity, levels of induction were compared with those of the -973 *rbcs ss3.6* promoter. The average of at least two to five experiments involving independently derived transformants is presented. The values presented are derived from experiments with cells transformed with chimaeric genes introduced using the *Agrobacterium* vector pGV3851.

Fig. 1 The construction of *ss-cat* chimaeric genes under the control of truncated pea *rbcs ss3.6* promoter fragments. Plasmids encoding truncated *ss-cat* genes are designated by the endpoints of the truncated promoter fragment. Plasmid pMH-973 is equivalent to plasmid pMH-2 (ref. 10). Amp^r , ampicillin resistance; Km^r , kanamycin resistance; \square , chloramphenicol acetyltransferase (*cat*) coding sequences; ∇ , nopaline synthase (*nos*) polyadenylation signal; \blacksquare , *rbcs ss3.6* promoter sequences.

Methods. An ~1-kb *Hind*III restriction fragment containing nucleotide sequences extending from 4 to 973 bp 5' to the mRNA cap site of the pea *ss3.6* gene and 30 bp of pBR327 was isolated from plasmid pPSR6¹⁹ and cloned into the *Hind*III site of pSVO-cat²⁰. To generate 5' deletions, the resulting plasmid was linearized by restriction with *Nde*I and digested with *Bal*31 exonuclease. The ends were repaired with Klenow fragment of DNA polymerase I and the products restricted with *Eco*RI. These fragments were cloned into the *Eco*RI/*Sma*I sites of M13 mp9 and the endpoints of the deletions determined by dideoxy sequence analysis²⁹. Appropriately sized fragments were removed by *Hind*III digestion, isolated by polyacrylamide gel electrophoresis and ligated into the unique *Hind*III site of pMH-1 (ref. 10). To prepare 3' deletions, the *ss3.6* promoter fragment was cloned into pBR322. The resulting plasmid was linearized with *Hind*III and digested with *Bal*31 exonuclease. The digestion products were restricted with *Bam*HI and the ends were filled-in with Klenow fragment of DNA polymerase. The plasmids were recircularized and HB101 transformants screened for regenerated *Bam*HI sites. One such transformant, determined by DNA sequence analysis to contain a deletion within the promoter extending from -4 to -90 5' to the cap site, was selected for further use. This 883-bp truncated promoter fragment was isolated and *Hind*III linkers were attached, then it was cloned into pMH-1.

Plasmid	Growth condition	% Conversion	Induction	Relative activity
pMH-973	Dark	1.1		
	Light	44.7	40.6	1.00
pMH-722	Dark	1.6		
	Light	13.5	8.7	0.21
pMH-357	Dark	1.9		
	Light	5.5	2.9	0.07
pMH-92	Dark	1.8		
	Light	3.8	2.1	0.05
pMH-973-90	Dark	0.1		
	Light	0.1	0.0	0.00

Fig. 3 The structure of chimaeric genes used to examine the effect of orientation and position of the *rbcS* upstream regulatory sequences when fused to their homologous or a heterologous promoter on photo-regulated *cat* gene expression. □, Chloramphenicol acetyltransferase coding sequences; ■, *rbcS* *ss3.6* promoter sequences; ▨, nopaline synthase promoter sequences; ▽, nopaline synthase polyadenylation signal. **Methods.** The construction of the various chimaeric genes was as follows. In plasmids pSWCAT-R1 and pSWCAT-W1, the 883-bp fragment (see Fig. 1) containing the *rbcS* *ss3.6* upstream regulatory sequences (–973 to –90 bp) was ligated into the *Hind*III site of pMH-92/39 either in the proper (pSWCAT-W1) or reverse (pSWCAT-R1) orientation to the direction of transcription. Plasmid pMH-92/39 was derived from pMH-92 (Fig. 1) by removing the *Hind*III site 3' to the *rbcS* *ss3.6* TATA box. In plasmids pMH-DEF1 and pMH-DEF2, a single copy of the 883-bp fragment to which *Bam*HI linkers were attached was inserted into the *Bam*HI site 3' to the *cat* coding sequence in pMH-92 (Fig. 1) either in the proper orientation to the direction of transcription (pMH-DEF1), or in the reverse orientation (pMH-DEF2). Chimaeric genes containing *ss-nos* promoter fusions were constructed as follows. Plasmid pNCAT-4²¹ was linearized by restriction with *Sac*II and digested with *Bal*31 exonuclease. The digestion products were restricted with *Hind*III, the ends filled-in with Klenow fragment of DNA polymerase, and the plasmids recircularized with T4 DNA ligase. HB101 transformants were screened for plasmids containing regenerated *Hind*III sites and one such transformant, pNCAT-M5, was determined by DNA sequence analysis³² to contain a truncated promoter extending 145 nucleotides 5' to the cap site. This plasmid was restricted with *Hind*II and the 883-bp *rbcS* upstream regulatory sequences inserted. In plasmid pSNCAT-R1, a single copy of the fragment is present in the proper orientation to the direction of transcription; in pSNCAT-W2 a tandem pair of fragments, both in the reverse orientation, has been inserted.

Expression of the truncated *ss-cat* chimaeric genes was determined by assaying levels of CAT enzyme activity in extracts from each independent dark- and light-grown transformed tobacco callus line (Fig. 2). Chimaeric genes under the control of the –973 promoter directed high levels (~40-fold induction) of photoregulated *cat* gene expression in light- versus dark-grown tissue, while deletion of sequences from –973 to –722 caused a dramatic loss of *cat* gene expression, levels of induction being ~20% of the –973 promoter level. Further deletion of sequences from the 5' end of the promoter resulted in additional loss of promoter strength, but did not abolish light inducibility. Truncated promoter fragments containing only 92 bp upstream from the mRNA cap site still directed photoregulated *cat* gene expression, albeit at greatly reduced levels (Fig. 2, pMH-92). The removal of sequences from –4 to –90, which includes the TATA box, resulted in the complete loss of both light and dark *cat* gene expression (Fig. 2, pMH-973-90). This promoter-less upstream fragment was also unable to direct transcription when cloned in the opposite orientation (data not shown).

Since integration of the T-DNA into the plant genome is a random process, variations in copy number and sites of integration might be expected to result in significant differences in levels of expression among individual chimaeric gene constructs. Estimates of copy number ranged from two to five copies per genome and independent transformants expressing the same chimaeric gene construct did not exhibit more than a twofold variation in levels of *cat* expression irrespective of whether the genes were introduced using pGV3851 or pTiC58 (data not shown) as vector. We prefer to accommodate these small differences by presenting levels of induction determined by comparing CAT activity in light- and dark-grown tissue derived from the same transformant.

To determine whether the upstream regulatory sequences required for high levels of photoregulated expression could act independently of orientation with respect to their homologous promoter, the chimaeric genes contained in plasmids pSWCAT-R1 and pSWCAT-W1 were constructed (Fig. 3). These chimaeric genes contain the *rbcS* *ss3.6* upstream regulatory sequences (an 883-bp fragment extending from –90 to –973 bp 5' to the cap site) fused to the truncated *rbcS* *ss3.6* promoter contained on plasmid pMH-92/39 either in the correct orientation to the

direction of transcription (pSWCAT-W1), or its reverse (pSWCAT-R1). In the correct orientation the fusion promoter essentially recreates the 'wild-type' –973 promoter.

The expression of pSWCAT-R1 and pSWCAT-W1 was assayed in light- and dark-grown transformed tobacco calli (Table 1). Chimaeric genes under the control of the truncated promoter fragments contained on plasmids pMH-92 (Fig. 2, pMH-92) and pMH-92/39 (not shown) exhibited only greatly reduced levels of photoregulated *cat* gene expression. However, chimaeric genes under the control of the promoter fusions contained on either pSWCAT-W1 (correct orientation) or pSWCAT-R1 (reverse orientation) showed approximately equal levels of photoregulated *cat* expression to those of the –973 promoter. Thus, these promoter fusions were capable of restoring wild-type levels of transcriptional activity to the –92 promoter. These observations indicate that *rbcS* *ss3.6* upstream regulatory sequences can direct high levels of photoregulated expression independently of their orientation relative to their homologous promoter.

The ability of the *rbcS* *ss3.6* upstream regulatory sequences to function independently of position relative to the TATA box and transcriptional start site was tested by placing these sequences 3' to the coding region of the *cat* gene under the control of the –92 *ss3.6* promoter (Fig. 3). Plasmids pMH-DEF1 and pMH-DEF2 contain chimaeric genes in which a single copy of the *ss3.6* upstream regulatory sequences has been placed at a 3' location either in the proper (pMH-DEF1) or reverse (pMH-DEF2) orientation to the direction of transcription. In dark-grown calli, the chimaeric genes contained on pMH-DEF1 and pMH-DEF2 exhibited levels of CAT activity similar to those observed for a *cat* gene under the control of the –92 promoter alone (Table 1). When these same constructs were assayed in light-grown calli, there was little or no apparent increase in levels of *cat* gene expression above that directed by the –92 promoter. These data indicate that for the constructs tested, the *ss3.6* upstream regulatory sequences cannot confer high levels of photoregulated expression when placed 3' to the TATA box and transcriptional start site.

These observations are similar to those recently reported for the upstream transcriptional regulatory sequences of yeast *GAL* and *CYC1* genes^{24,25}. These yeast regulatory sequences function

independently of orientation 5' to the TATA box and transcriptional start site, but fail to activate transcription when placed 3'. These observations led to the suggestion that the yeast regulatory sequences may differ mechanistically from other known enhancers²⁵. The *rbcS* upstream regulatory sequences may similarly possess fundamental differences. Alternatively, the potential activity of the *rbcS* upstream regulatory sequences may be blocked by elements residing between them and their site of action when in this 3' location^{12,24-26}.

Since sequences within the -92 *rbcS ss3.6* promoter direct low levels of photoregulated expression independently of additional upstream sequences, it may be argued that the upstream regulatory sequences are not involved in mediating light inducibility, but are involved only in determining absolute levels of expression. To test this directly, we fused the *rbcS ss3.6* upstream regulatory sequences to the normally non-photoreponsive¹⁰ promoter from the nopaline synthase (*nos*) gene²⁷ (Fig. 3). In these fusions a *nos-cat* chimaeric gene (Fig. 3, pNCAT-M5) was used containing a truncated *nos* promoter in which all but 145 bp 5' of the mRNA cap site have been deleted. This truncated promoter retains the 'TATA' and 'CAAT' boxes²⁷ and is capable of directing wild-type levels of *cat* expression in light- and dark-grown transformed tobacco calli (Table 1), consistent with previous observations²⁸.

Table 1 Chloramphenicol acetyltransferase activity in extracts from light- and dark-grown transformed calli expressing chimaeric genes used to test for enhancer-like activity of *rbcS* upstream regulatory sequences

Plasmid	Growth condition	% Conversion	Induction	Relative activity
pSWCAT-R1	Dark	1.4		
	Light	53.0	37.9	0.93
pSWCAT-W1	Dark	1.1		
	Light	41.1	37.2	0.92
pNCAT-4	Dark	5.6		
	Light	4.0	0.0	0.00
pNCAT-M5	Dark	3.9		
	Light	4.4	0.0	0.00
pSNCAT-R1	Dark	3.2		
	Light	53.2	16.6	0.41
pSNCAT-W2	Dark	4.6		
	Light	62.7	13.6	0.33
pMH-DEF1	Dark	1.1		
	Light	5.2	4.7	0.12
pMH-DEF2	Dark	1.2		
	Light	4.6	3.9	0.09

Chloramphenicol acetyltransferase activity was assayed and quantitated as described in Fig. 2 legend. Plasmid designations correspond to the chimaeric genes described in Fig. 3. The values presented are derived from experiments using cells transformed with chimaeric genes introduced using the *Agrobacterium* vector, pGV3851.

The chimaeric gene encoded by pSNCAT-R1 contains a single copy of the *ss3.6* upstream regulatory sequences fused to the truncated *nos* promoter in the proper orientation to the direction of transcription and at approximately the same distance upstream from the *nos* transcriptional control sequences as naturally found in the *ss3.6* promoter. In pSNCAT-W2, a tandem pair of the upstream regulatory sequences, both in reverse orientation to the direction of transcription, are present.

In dark-grown calli, the chimaeric genes encoded in pSNCAT-R1 and pSNCAT-W2 each showed similar levels of *cat* expression to those observed for either the wild-type or truncated *nos-cat* gene (Table 1). This suggests that the *ss3.6* upstream regulatory sequences do not alter dark levels of expression of these genes. As expected¹⁰, on transfer to light neither the wild-type nor truncated *nos-cat* gene showed altered levels of *cat* expression. Chimaeric genes containing the *ss-nos* promoter fusions (pSNCAT-R1 and pSNCAT-W2), however, exhibited

dramatic increases in *cat* gene expression in light- versus dark-grown calli (Table 1). Thus, chimaeric genes containing the *ss-nos* promoter fusions exhibit the same photoregulation observed for the *rbcS ss3.6* promoter. Comparison of *ss-nos* promoter fusions and the -973 *ss3.6* promoter construct revealed that the absolute levels of *cat* expression in the light are similar. However, induction levels for both pSNCAT-R1 and pSNCAT-W2 are ~50% of those observed for the -973 *ss3.6* promoter construct, due to the higher levels of CAT activity in dark-grown calli expressing genes containing the *ss-nos* promoter fusions. Placing the *ss3.6* upstream regulatory sequences inverted and in tandem did not affect the levels of induction when compared with a single correctly oriented copy fused to the truncated *nos* promoter. These results demonstrate that the upstream regulatory sequences can mediate photoregulated expression independently of additional transcriptional signals found within the -92 *rbcS ss3.6* promoter.

We have demonstrated clearly that sequences upstream of the *rbcS ss3.6* TATA box both contain information necessary for maximum levels of expression and confer photoregulation. The *rbcS ss3.6* upstream regulatory sequences function independently of orientation when fused to either their homologous or a heterologous promoter. As these upstream regulatory sequences alone are unable to promote expression when joined directly to the *cat* coding sequence (Fig. 2), we presume that the enhanced expression observed from the fusion promoters reflects an increase in the level of transcripts initiated from the normal start site. Experiments to test this directly are in progress. We conclude that the expression of the plant *rbcS ss3.6* gene is regulated by a genetic element that is similar in many respects to the animal viral and cellular enhancers¹²⁻¹⁸. The ability of the *rbcS* enhancer-like element to function when fused to a heterologous promoter will facilitate its characterization. Moreover, the ability of the *rbcS* and related enhancer-like elements to modulate expression via heterologous promoters is likely to prove useful in the genetic manipulation of plant species.

We thank L. Szabo and R. Hellwig for critical reading of this manuscript, J. M. Hand for help in various aspects of these studies, and P. Cashmore for technical assistance. Reverse transcriptase activity and Ty RNA are associated with virus-like particles in yeast

The Ty element of yeast represents a class of eukaryotic transposons that show remarkable structural similarity to retroviral proviruses^{1,2}. Recently, these comparisons have been strengthened by a series of observations on the yeast Ty element: (1) Ty transposes via an RNA intermediate³; (2) it contains a sequence (Fig. 1) which, when translated, is homologous to a conserved region found in all reverse transcriptases^{4,5}; (3) a fusion protein encoded by Ty is produced by a frameshift event that is directly analogous to the production of Pr180^{gag-pol} in a retrovirus such as Rous sarcoma virus^{5,6}. Here we identify the reverse transcriptase activity that, until now, has been presumed to mediate Ty transposition and show that it is sequestered in virus-like particles that also contain Ty RNA.

Most Ty elements are about 5.9 kilobases (kb) long with long terminal repeats (LTRs), called delta (δ) sequences, of ~335 base pairs (bp). The major transcript (5.7 kb long) starts at the *Xho*I site in the 'left' or 5' δ and ends ~50 nucleotides beyond the *Xho*I site in the 'right' or 3' δ ^{7,8}. At the 5' δ -internal sequence junction there is a sequence that could base-pair with the 3' end of a tRNA^{Met} molecule⁹, producing a potential primer-template substrate for reverse transcriptase analogous to that used by retroviruses¹⁰. The transcriptional unit is divided into two open reading frames, designated *TYA* and *TYB*, which overlap in different reading phases by 38 nucleotides^{5,6,11}. *TYA* encodes a protein, designated p1, of relative molecular mass (M_r) ~50,000 (50 K)^{6,12}. *TYB* is expressed, via a frameshift event^{5,6}, as a *TYA/TYB* fusion protein (designated p3) of M_r ~190 K¹³. Protein p3(Ty1-15) appears to be processed, and a likely product is a 50 K protein designated p2 (ref. 13). The structure and internal organization of the element used in this study, Ty1-15 (ref. 14), is shown in Fig. 1A.

The striking similarities with respect to structure and expression strategy of Ty and retroviruses suggests that the analogy may include the formation of retrovirus-like particles containing Ty RNA; this is apparently the case for the related *copia*-like elements of *Drosophila* which have been reported to produce virus-like particles (VLPs) containing *copia* RNA and reverse transcriptase activity¹⁵. To test this idea for Ty we used the powerful approach of massive overexpression of a Ty transcriptional unit in a high-efficiency yeast expression vector. (We have used this approach previously to identify Ty-encoded proteins^{11,12,13}.) The entire transcriptional unit of Ty1-15 was manipulated to form a convenient *Bam*HI fragment which was then inserted into the *Bgl*II expression site of plasmid pMA91 (refs 16, 17) (Fig. 1B), the resulting plasmid, pMA91-10, drives Ty expression from the promoter of the yeast phosphoglycerate kinase (*PGK*) gene such that Ty1-15 RNA levels are 20-fold higher than that directed by all the endogenous 35 copies of Ty in the genome¹². The construction and authenticity of pMA91-10 have been described previously¹². If Ty produces VLPs there should be many more present in yeast strain T91-10, containing pMA91-10, than in a control strain, T91, containing vector alone. To test this notion, thin sections of the two strains were examined directly in the electron microscope (Fig. 2A, B). In T91-10 there were large numbers of spherical VLPs of ~60 nm diameter

Fig. 1 A, Organization of Ty1-15. Solid boxes, δ sequences. Thick line, internal ϵ region. The major 5.7-kb transcript is indicated. The *TYA* gene extends from nucleotide 299 to 1,619 (ref. 3). The *TYB* gene extends from nucleotide 1,581 to 5,676 (ref. 4 and Fulton *et al.* unpublished data). *TYA* codes for the 50 K protein p1 (Ty1-15)^{6,12,13}. *TYB* is expressed as a *TYA/TYB* fusion protein of M_r ~190 K, p3 (Ty1-15), via a specific frameshift event^{5,6}. AP, region complementary to the 3' end of tRNA^{Met}⁹. AP, region homologous to the active site of acid proteases and retroviral processing proteases³²; RT, region homologous to the conserved region of reverse transcriptases^{4,5}. B, Structure of pMA91-10. The *Xho*I fragment from Ty1-15 was converted to a *Bam*HI fragment (designated fragment 10) as described previously¹² and inserted into the expression vector pMA91 (ref. 16). Plasmid pMA91 is a pBR322 (thin lines) derivative containing a *LEU2*/2 μ origin selection and replication module from pJDB219 (ref. 40) (solid box), the 5' promoter region from the yeast *PGK* gene (open box) and the 3' transcription terminator fragment from the yeast *PGK* gene (hatched box). The *PGK* 5' and 3' regions flank a *Bgl*II expression site. The arrow indicates the direction of transcription promoted by the *PGK* 5' region. X, *Xho*I; Bg, *Bgl*II; R, *Eco*RI; B, *Bam*HI; H, *Hind*III.

whereas in the control strain, T91, there were very few if any. All sections of T91-10 contained particles, which were generally densely packed and represented between ~20% and 80% of the surface area of the sections. The particles appeared to be cytoplasmic and were distributed widely. The difference in numbers of VLPs between the two strains strongly implicates Ty in their formation and we suggest that these particles be designated Ty-VLPs.

If the Ty-VLPs are truly analogous to retroviral particles, they should possess Ty RNA and reverse transcriptase activity¹. Extracts of T91-10 and T91 were therefore fractionated on 15–45% sucrose gradients and the fractions assayed for reverse transcriptase activity and Ty RNA. Initially the reverse transcriptase assay assumed that there would be an endogenous substrate comprising the Ty RNA with a tRNA^{Met} primer annealed to it via the homology at the δ - ϵ junction⁹, although it should be emphasized that there is no direct evidence for this tRNA acting as a primer in this context. A large peak of putative reverse transcriptase activity was found at a gradient position corresponding to a particulate fraction of ~175 S from T91-10 (Fig. 3A); a smaller peak was obtained from the T91 extract. Coincident with this peak of putative reverse transcriptase activity was a peak of full-length Ty RNA (Fig. 3A), suggesting that, as predicted, the 175 S particles contain both the enzyme

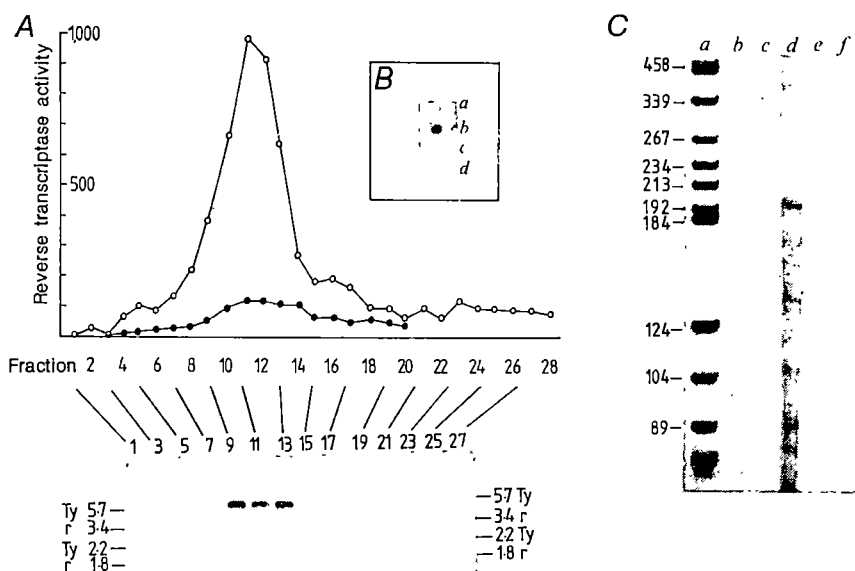

Fig. 2 Electron microscopy of Ty-VLPs. **A**, Thin section of T91-10 ($\times 7,800$). P, Area containing predominantly Ty-VLPs; R, area containing predominantly ribosomes. **B**, Thin section of T91 ($\times 7,800$). Ribosomes can be seen over most of the section. **C**, Uranyl acetate-stained Ty-VLPs from pelleted fractions of a T91-10 extract (low magnification, $\times 30,160$; high magnification, $\times 72,800$).

Methods. Thin sections were prepared according to the method of Byers and Goetsch⁴¹. Purified particles were prepared for electron microscopy by placing 5 μ l of the resuspended pellet on a Formvar/carbon-coated grid and allowing the particles to settle for a few minutes, after which a drop of 2% glutaraldehyde was added, followed by two or three drops of aqueous uranyl acetate. The sections were observed in a Phillips 410 transmission electron microscope.

Fig. 3 **A**, Sucrose gradient fractionation of extracts of T91-10 and T91. The plot shows reverse transcriptase activity in c.p.m. bound to DE81 paper (see below) in fractions from 15–45% sucrose gradients containing material from T91-10 (\circ) and T91 (\bullet). Below the profiles are shown autoradiographs of Northern blots of RNA isolated from the fractions, bound to nitrocellulose and then probed with nick-translated^{1,42} Ty DNA. The positions and sizes of two ribosomal RNA markers (r) and two Ty RNAs (Ty) are marked. **B**, Dot-blot analysis of reaction products. Reverse transcriptase reaction products were hybridized to four DNA spots: a, no DNA; b, Ty DNA (pAT153-11, which comprises pAT153 containing the left-most *Xho*I–*Bgl*III fragment of Ty1–15; see Fig. 1); c, rDNA (pYRG12)⁴³; d, pAT153 DNA⁴⁴. **C**, Labelled endogenous reaction products separated on a sequencing gel: a, M_r markers; b, reaction with low concentration (1 μ M) of cold dNTPs; c, 32 P-labelled dTTP replaced by 32 P-labelled UTP; d, standard reaction (100 μ M cold dNTPs); e, standard reaction followed by treatment with DNase I (50 μ g ml⁻¹; Worthington); f, reaction with no cold dNTPs.

Methods. VLPs were isolated as follows. Yeast cells were grown selectively at 30 °C to a density of $5\text{--}8 \times 10^6$ cells ml⁻¹. The cells were then collected by low-speed centrifugation, washed once in water and resuspended in TEN buffer (10 mM Tris pH 7.2, 2 mM EDTA, 100 mM NaCl) at 1 ml per 1 cells. The cells were disrupted by vortexing with glass beads (40-mesh; BDH) at 4 °C until >70% were broken, then the supernatant was removed and sonicated 10 times on ice for 15 s (6–7 μ m peak-to-peak). The debris was removed by centrifugation (40,000 g for 1 h at 4 °C), and the supernatant layered onto a 15–45% (w/v) sucrose gradient in 10 mM Tris pH 7.2, 10 mM NaCl and spun at 76,300 g for 3 h at 15 °C. Fractions were collected through the bottom of the tube and assayed for reverse transcriptase activity. The endogenous substrate assay was an adaptation of the method of Goff *et al.*⁴⁵. 10 μ l of sample, usually an undiluted sucrose fraction, was added to 20 μ l of an assay cocktail to give the following reaction concentrations (in mM): 50 Tris-HCl pH 8.3, 20 dithiothreitol, 0.6 MnCl₂, 2 MgCl₂, 60 NaCl, 0.1 dATP, 0.1 dCTP, 0.1 dGTP, and 0.06 U ml⁻¹ RNasin (P & S Biochemicals), 0.05% NP40, 0.02 μ Ci μ l⁻¹ [α -³²P] TTP (400 Ci mmol⁻¹; Amersham). This mixture was incubated at 20 °C for 2 h, after which 15 μ l of each assay was transferred to a DE81 filter (Whatman). The filters were washed three times in 5% Na₂HPO₄ for 15 min, once in water, twice in ethanol, then allowed to air-dry. The filters were then counted in a scintillation counter. Products of the endogenous substrate were analysed as follows. ³²P-labelled products were extracted twice with phenol/chloroform (1:1) in TEN, 0.1% SDS and precipitated with 2.5 vol. ethanol, 0.2 M potassium acetate at –70 °C. The precipitate was resuspended in hybridization buffer, added to the DNA filters (see below), incubated overnight at 42 °C and washed twice for 1 h in 2 \times SSC, 20 mM PO₄, 0.1% SDS. Filters were exposed to film at –70 °C with two intensifying screens. RNA isolation and Northern blotting were carried out as described previously¹². DNA was dot-blotted onto nitrocellulose according to Kafatos *et al.*⁴⁶. Detailed analyses (see Figs 2 and 4) were carried out on particles that had been repurified on a second sucrose gradient (25–45%) and then pelleted at 100,000g. S values for the particles in the peak fractions were obtained by re-running the fraction in a Beckman Model E analytical ultracentrifuge.

Fig. 4 Ty-VLP proteins, **A**, Coomassie blue-stained proteins from T91-10 (lane 1), isolated Ty-VLPs (lane 2) and T91 (lane 3). The p1 and p2 proteins in T91-10 and the 70K and 50K proteins from the Ty-VLPs are marked. **B**, DNA-binding profiles of the proteins in **A** electroblotted onto nitrocellulose and probed with 32 P-labelled yeast DNA. Lanes 1-3 same as for **A**. The arrows mark the three major dsDNA-binding proteins present in yeast extracts.

Methods. VLPs were isolated as described in Fig. 3 legend. Pelleted gradient fractions (see Fig. 3 legend) were diluted fivefold with 10 mM Tris pH 7.5, 10 mM NaCl and precipitated for 2 h at -70°C after the addition of 2 vol. cold acetone and NaCl to a final concentration of 0.1 M. The precipitates were resuspended in Laemmli buffer⁴⁷, boiled for 5 min and loaded onto a 9% acrylamide/bis (30:1.6) gel with a 5% stack. The gel was stained with Coomassie blue. DNA-binding assays were performed as described previously¹³ and followed a procedure similar to that described by Bowen *et al.*⁴⁸. Nick-translated⁴² total yeast DNA was used in the assay.

and its template. In addition to the full-length RNA, a 2.2-kb Ty RNA was present in the particles. A Ty RNA of approximately this size has been reported by Taguchi *et al.*¹⁸ but its function is unknown. The peak fractions (10-13 in Fig. 3A) were pooled and examined in the electron microscope (Fig. 2C); Ty-VLPs like those seen in the thin sections were present in the pooled fractions. The particles were relatively pure, the major contaminant being membrane fragments. They appear to be composed of a central core and an outer shell. There were no such particles in fractions 5 and 18.

The putative reverse transcriptase activity was characterized in various ways. The labelled products of the endogenous assay were run on a sequencing gel and shown to be a heterogeneous collection of fragments a few hundred nucleotides long (Fig. 3C). These products, which disappeared totally after treatment with DNase, were substantially reduced if a 100-fold lower concentration of dNTPs was used, and were absent if no dNTPs were added to the reaction. Furthermore, no such products were seen when 32 P-UTP was used as the labelled species. It is likely, therefore, that these products are DNA derived from a sub-optimal reaction. In a dot-blot hybridization experiment which compared the hybridization of the products to Ty, ribosomal and plasmid pAT153 DNA, the products hybridized predominantly to the Ty DNA dot (Fig. 3B). The low degree of hybridization to the ribosomal dot was due to small amounts of contaminating ribosomal RNA throughout the gradient (data not shown). These data show that the activity in the peak fractions incorporates deoxynucleotides preferentially into Ty DNA. Table 1 lists some of the properties of this activity. Incorporation in the endogenous assay is reduced by 76% after pretreatment with RNase, suggesting that a component of the endogenous substrate is RNA; that the activity is only partially sensitive to RNase may be due to protection of the RNA template by the particles. Similar results have been obtained by others^{15,19-21}. An activity profile similar to that of the endogenous assay (Fig. 3A) was also seen with poly(rC)-oligo(dG), poly(rCm)[poly(2'-O-methylcytidylate)]-oligo(dG) and poly(rA)-oligo(dT) primer-template substrates; peak activities for these are shown in Table 1. Poly(rC)-oligo(dG) is a poor substrate for DNA-dependent DNA polymerases, while

poly(rCm)-oligo(dG) is not used at all as a substrate for these enzymes^{22,23}. Furthermore, the endogenous reaction is resistant to treatment with actinomycin D, which inhibits DNA-dependent polymerases. These results suggest strongly that the activity associated with the Ty-VLPs is not a DNA-dependent DNA polymerase. In the poly(rC)-oligo(dG) assay the activity is dependent on both primer and template and does not incorporate significant amounts of 32 P-TTP. These data show that the incorporation of label does not occur via some nucleotide transferase activity. Taken together, these observations strongly suggest that the activity associated with Ty-VLPs is a reverse transcriptase.

Retroviral reverse transcriptase activity is dependent on the presence of divalent cations. Different enzymes show different optima for Mn^{2+} and Mg^{2+} (ref. 24), similarly, the activity associated with Ty-VLPs is totally dependent on the presence of either Mn^{2+} or Mg^{2+} . Retroviral reverse transcriptases are usually liberated from particles by disrupting the viral envelope with detergent²⁰, therefore the activity of the retroviral enzymes *in vitro* is dependent on detergent treatment. When Nonidet P-40 (NP40) was omitted from the Ty endogenous assay there was a reduction of activity of only ~50%. This difference between the Ty-VLP and retroviral systems may be due to the absence of an envelope structure in Ty-VLPs (see below). The Ty-VLP enzyme has a temperature optimum of $\sim 20^{\circ}\text{C}$ although there is not a marked peak of activity; this is compatible with the observation that Ty transposition occurs most frequently at about this temperature²⁵. A detailed comparison of retroviral and Ty enzymes awaits purification of the Ty enzyme and the definition of conditions that reproduce the *in vivo* activity *in vitro*.

As a first step towards the analysis of the protein composition of these Ty-VLPs, we set out to determine whether the particles contained proteins that we had previously recognized as being Ty-specified^{6,12,13}. Peak fractions from the gradients were pooled, repurified on a second sucrose gradient (25-45%) and concentrated by pelleting the particles. The dissociated particle proteins were then run on SDS-polyacrylamide gel electrophoresis (PAGE) alongside a yeast extract known to contain high levels of Ty proteins¹³. Two major protein species of ~70 K and ~50 K are just visible in the stained gel profiles (Fig. 4A). The rather broad 50 K band co-migrates with the previously identified p2 protein in the T91-10 extracts. Protein p2 is one of the few yeast proteins that binds double-stranded (ds) DNA in a blot-binding assay¹³. Therefore, we asked whether the 50 K protein from the purified particles could bind dsDNA. Figure 4B shows that the p2 DNA-binding band that is present

Table 1 Properties of the Ty-VLP reverse transcription

Assay	Variation	c.p.m. incorporated	Activity
Endogenous		2,249	100
	-Mn - Mg	50	2.2
	-NP40	1,086	48.2
	+Actinomycin D	2,259	100.4
	+RNase	547	24.3
	Incubation at 10°C	1,725	76.7
	Incubation at 30°C	1,927	85.6
	Incubation at 37°C	1,443	64.1
	Incubation at 42°C	1,041	46.2
Poly(rC)-oligo(dG)		4,188	100
	- 32 P-GTP + 32 P-TTP	56	1.3
	-poly(rC)	132	3.2
Poly(rCm)-oligo(dG)	-oligo(dG)	172	4.1
		2,505	100
Poly(rA)-oligo(dT)	- 32 P-GTP + 32 P-TTP	41	1.6
	-	2,140	100

The endogenous substrate assay is described in Fig. 3 legend. Additions to the endogenous assay were actinomycin D ($100\text{ }\mu\text{g ml}^{-1}$) and RNase A ($100\text{ }\mu\text{g ml}^{-1}$). Exogenous substrate reactions were the same as the endogenous assay except that either $10\text{ }\mu\text{g}$ of poly(rA) (Calbiochem) and $0.1\text{ }\mu\text{g}$ of oligo(dT) (Collaborative Research) or $10\text{ }\mu\text{g}$ of poly(rC) (Calbiochem) and $0.1\text{ }\mu\text{g}$ of oligo(dG) (Collaborative Research) or $2\text{ }\mu\text{g}$ of poly(rCm)-oligo(dG) (1:1 molar nucleotide ratio) (P.L. Biochemicals) were present in each assay instead of the cold deoxynucleoside triphosphates. 32 P-GTP was used instead of 32 P-TTP in the G-C reactions.

in T91-10 but absent from T91 co-migrates with a band from the purified particles. These data strongly suggest, therefore, that the Ty-VLPs contain p2. The nature of the 70 K protein, however, is unclear.

The discovery of reverse transcriptase associated with a VLP that contains Ty RNA provides the first protein components in a mechanistic model of Ty transposition. Presumably, as is the case for retroviruses, the enzyme catalyses the production of the dsDNA form of the element from the full-length particle-bound RNA template and tRNA^{Met} primer, and then integration could be mediated by an endonuclease. In retroviruses this endonuclease derives from a post-translational cleavage of the primary *pol* product²⁶⁻³¹; it remains to be seen whether the same is true for Ty. Irrespective of the enzymological details, it must be established whether the Ty-VLPs act as units of transposition or are simply the result of an obsolete viral packaging pathway that is perhaps conserved to sequester the potentially chaotic reverse transcriptase away from cellular RNAs.

Recent observations^{3-6,32}, and the data presented here, appear to establish a close relationship between Ty and retroviruses. However, a comparison of the genomic organization of Ty with that of a generalized retrovirus reveals a major difference. Most retroviruses contain three major protein-coding regions: *gag*, which codes for the viral core components; *pol*, which encodes the reverse transcriptase and integrative endonuclease; and *env*, which codes for viral surface components². *TYA* and *TYB* correspond, in position, to *gag* and *pol* respectively, but Ty appears to lack an *env* region. Thus, Ty may be considered a 'defective retrovirus' and its lack of *env* may explain its relatively small particle size (60 nm as opposed to 80-120 nm for retroviruses³³), *env* may have been lost because it was not needed after some ancestral retrovirus found itself trapped within the walled yeast cell. Alternatively, it may not have evolved because selection for such a structure would not have occurred in a particle without an extracellular stage.

Intracellular retrovirus-like particles have been identified in other systems. The most notable are the A-type particles seen in mouse cells³⁴ and the VLPs that contain *copia* RNA and reverse transcriptase activity in *Drosophila*¹⁵. It seems feasible, therefore, that the distribution of this class of genetic elements may be as broad as that of authentic retroviruses. These elements may be responsible for a wide range of genomic rearrangements, gene activation phenomena and the generation of various reverse-transcribed products such as intronless pseudogenes³⁵⁻³⁷ and the human *Alu* repeats³⁸.

We thank Guy Cox, Barrie Juniper and Ray Newsam for assistance with the electron microscopy. This work was supported by a MRC project grant (G8317537CB) (to A.J.K. and S.M.K.), a SERC research studentship (to M.H.M.) in Oxford and SERC grant (GR/C/32027) (to K.G.) in Kent.

Following submission of this paper, similar results were published by Garfinkel *et al.*³⁹.

Winning flexibility for research

The largest of the British research councils has produced a corporate plan that dodges all the hard questions. Here is a question that it cannot avoid much longer.

THE variety of names under which British organizations now canvass their hopes and aspirations has become bewildering. In the old days, before 1980, it was by no means unusual that research organizations such as the five British research councils would put out documents called "plans" or, a little more pretentiously, "strategies", from which interested readers might tell what might lie ahead. More recently, it has been the custom for the research councils to prepare each year a document called a "forward look" intended to accompany and sustain their annual requests for government funds. But now, in deference to the British government's conviction that research should be a branch of business, "corporate plans" are all the rage. The Agricultural and Food Research Council was the first in the field nearly a year ago. Now it has fallen to the Science and Engineering Research Council (SERC) to publish (see p.589) a document with such a title, but which is otherwise such a pale imitation of what a commercial corporation would put out under such a heading that there is a danger that the new currency will be debased even before its meaning has been generally understood.

SERC is worried about money, and for a good reason, as it has been for the past several years. The document published this week has its origins in the sense of panic that overtook the council in the autumn of 1984, when it was decided that nothing less than a radical reappraisal of the council's activities would suffice to make ends meet. It had already then been decided that British membership of the European high-energy physics enterprise (CERN) should be reconsidered. SERC off its own bat resolved to decide whether two home-based research observatories were needed to support activities at the overseas observatories, those with real telescopes. And there was to be a reappraisal of the fields of science in which the council would concentrate its future efforts. By all accounts, the steam went out of the enterprise when it was found that the budget for the current year would not be as meagre as at first feared, partly because of a share of the extra £15 million quarried by Sir Keith Joseph, the Secretary of State for Education and Science, from thin air, but at the expense of his political standing with his colleagues. Then, in the summer, came a new chairman and no fewer than seven new members of the council, no more willing to be bound by their predecessors' decisions (and prevarications) than would be a commercial board. The result is a document that still pleads the need for radical reappraisal, which nevertheless still lies somewhere in the future.

Because reappraisal is altogether too important for the health and welfare of the British research community to be left indefinitely on the shelf, and since SERC's problems are not in essence different from those of the other research councils operating in support of basic science in Britain, the new council should face up to the problems it and its predecessors have endlessly defined. The difficulty is that SERC has lost flexibility over the years by the growth of its apparently unavoidable commitments. The commitment to CERN, £35.5 million last financial year, which fluctuates with the value of sterling, is the most conspicuous of these. The two British-based observatories are another constraint on flexibility, and their future may be clearer when the committee on the subject under Sir John Kingman produces its report next year. But the end result is that, out of a total budget of £291 million in 1984-85, SERC was

able to spend only £79 million on research grants and £46 million on research fellowships of various kinds. Where has the rest of the budget gone? The conspicuous commitments are not the only restraints on the council's flexibility. The second largest item in SERC's budget, after research grants, is the cost of the establishment known as the Rutherford Appleton Laboratory (RAL), on the site of the now defunct NIMROD proton accelerator, where some 1,400 professional people provide support services for research in the physical sciences undertaken by the academic community. Should not a truly radical reappraisal consider whether such a large establishment, ostensibly for servicing grant spending which is nearly identical in amount, should continue to exist in its present form?

None of this should be read as a complaint against the laboratory or its staff. By demonstration over the past several years, they have done a splendid job in a variety of important fields. The laboratory is the chief centre in Britain for the development of instruments to be flown in Earth satellites in the pursuit of basic research. It is a computing centre of great value to the British academic community and also a source of innovation in the field. In its own right, the laboratory has an important programme of ionosphere and atmosphere research, a legacy of the merging of the old Appleton laboratory with the old Rutherford laboratory a decade ago. And RAL continues to mastermind some parts of nuclear physics, managing the spallation source that is now the chief source of academic neutrons in Britain. All this, and much else, has been done well. But SERC should ask itself whether such an establishment is, in present circumstances, more of a hindrance than a help.

The arguments for a change at RAL are powerful. As a laboratory whose chief function is to service academic research for the whole of a national research community, RAL is distinguished and probably also unique; nowhere else has such an all-purpose establishment been found necessary or thought wise. The most obvious difficulty is that a commitment on this scale to skilled people, however flexible they may be individually, cramps the council's strategic flexibility. Moreover, it is no longer likely that the work now sited at RAL is all of a kind that must be done centrally because "size and complexity" would overwhelm university sites at which it might be placed. And while SERC's corporate plan boasts modestly of some contract work for industry, when universities are as hungry as they are at present, it is much more likely that technology would be quickly transferred from where it is created if it had sprung from university laboratories, not centralized institutions.

Reading between the lines of the corporate plan, the council plans to be more timorous. There is talk of an agreement with the unions that 10 per cent of the staff at RAL might be on short-term contracts (but the quota has not yet been taken up). What SERC should be planning is a scheme for devolving as much as possible of the work that it does at RAL to universities. Just now, there is a further possibility that some part of RAL might be spun off to the new space centre on which the British government has set its heart. The dangers of such a move are clear in people's minds, but the advantages of the flexibility that could result are greater. The real danger, for SERC, is that it cannot convincingly threaten CERN and its observatories with the knife if the largest of its establishments remains untouched. □

Holding to tenure

The British government and British academics are both misguided on the tenure system.

THE howls of protest that might have been expected after last week's announcement that the British government is to fulfill its threat to abolish academic tenure have been surprisingly muted. Is it perhaps that academics know that it will not be them, or most of them, who will be affected, but their successors? But although the issue is for the time being relatively silent, there is every prospect of trouble when the bill that Sir Keith Joseph promised he would be introducing to the House of Commons later in the parliamentary session begins its passage. For the government's proposals will engender legislation of the worst kind, schemes for putting wrongs (which there are) to rights which are engendered not by a sober consideration of what needs to be done, but by animus. The best outcome would be that one or other of the houses of parliament should throw out what the government proposes, substituting legislation that would give it what it has a right to ask for — and giving academic institutions their just needs at the same time.

Sir Keith Joseph first advertised his plans early last summer. The problem he intends to tackle is the way in which many (but not all) contracts of employment between universities and their academics include the provision that people will have the right to stay at work until their normal retirement age unless previously dismissed for misconduct defined by a narrowly drawn list of misdemeanours. Because the constitution of British universities is defined by means of separate royal charters, legally untouchable by parliament, unless those governed by the charters (which means academics) choose to amend them, parliament and thus the government can act only indirectly, by persuading the Privy Council (the monarch's secretariat) to appoint commissioners with powers to amend the charters one by one. It is a fair guess that this decade will be out before the job is done, which is one reason why an ageing academic workforce may not be too alarmed. But the amendment that the minister now proposes has the further defect that it will apply only to some academics, those newly appointed or those who have the good fortune to be promoted from one grade in the hierarchy to another. So, for a transitional period that will last until the year 2025 or thereabouts, there will be two kinds of British academics — those with tenure and those who do not have it. Tidy government needs something better.

What the government has consistently failed to acknowledge is that academic tenure has a purpose, that of making sure that individual academics are not victimized for unorthodox opinions, a pitfall into which the most imaginative and ultimately the most valuable scholars are prone to fall. Nothing in what the government now proposes will change that state of affairs. What will happen is merely that younger academics in pursuit of unorthodox lines of enquiry will more easily be shown the door by conservative heads of department. Most senior academics, of course, will be too sensible for that, but that is not much of a safeguard against the consequences of the tetchy intellectual enmity that so often blows up in university atmospheres. In this respect, tenure is a necessary and valuable safeguard against intellectual injustice. It is shabby that the British government has let its resentment of the idea that academics "have a job for life" cloud its judgement about the need for a measure of academic freedom. Animus has got the better of it.

But none of this implies that tenure should be inviolable. That is the point at which academics are often wrong. If universities are, or wish to be, self-governing institutions, they must also be free to change course from time to time. If, for example, there should be no students wishing to read Sanskrit at the university at which it is best taught, the university must at least be free to decide whether the department concerned, and those who teach in it, should be dispensed with. Naturally, it would be again be shabby if a university, having seen the demand for Sanskrit fall to nothing, should be able to write out dismissal notices on the

spot, without further consultation. No academic institution seeking respect elsewhere could behave in such a cavalier fashion and then hold its head up (or attract other academics). Even in a free market, scholarship is worth paying for. To ensure that decisions such as these are made in a seemly fashion, two considerations must be satisfied. Universities must be well governed domestically, so that even the victims of hard decisions may feel they have participated in them. And universities must have enough autonomy, financially as well as legally, for good internal government to carry conviction.

How is that to be accomplished? This is where the British government is especially vulnerable to rational complaint. For the past five years, universities have been forced to live financially from hand to mouth. Even at this stage in the current academic year, British universities do not know what subsidy they will be given by the government in the year beginning eight months from now. They will not know for sure until the spring. How, in such circumstances, can universities pretend to themselves, and to those who work for them, that they are self-governing and autonomous? And even if the government is only playing cat-and-mouse with its universities, hoping to keep them hopping with uncertainty, how can it be sure that some of its assets will not give way under the strain? If the government had been more moderate on this contentious issue, it would probably have been able to win what it wants without the fuss now in prospect. What it needs is not a law but a deal, one in which the universities would trade a reasonable self-determined restraint on tenure for a measure of financial security of the kind the government has perversely chosen to deny them. If the government had followed that path, it might even have found falling into its lap the prize it has not yet dared to ask for — the abolition of the doctrine that academics should all be paid the same salaries (at the same age), however successful (or otherwise) the institutions at which they work. □

Poor solstice

Nature's annual weekly break coincides with the break in the calendar, on this occasion by design.

THE New Year festival is of course discriminatory. Its psychological significance is that of the winter solstice; *reculer pour mieux sauter* is the motto, which discriminates against those living in the Southern Hemisphere and even in the tropics. In due course, it will be acknowledged that an equinoctial break (but which?) would be more equitable. Meanwhile, the old northern conventions persist, even to gloomy Nordic reflection on the past and speculation about what lies ahead.

Here is how that train of thought might go. In retrospect, 1985 has been a teasing year. One proof of that is the Geneva summit, which happened; the let-down is that nothing much happened when it did. The US space shuttle has gone up and returned with great regularity (Ariane less reliably), but the seemingly quite recent excitement about journeys within the Solar System has been overshadowed by evidence of the physical weakness of people's hearts and minds.

Science in the year past was a fine-textured business. Umpteen more nucleotide sequences cram the databanks, but there are only a couple of extra biogenetic chemicals on the market, and just a handful of gene probes that might spot congenital disease in advance. Most people have learned that, with computers, the software is more important than the hardware — and have taken to complaining about the former. No new fundamental particles have been found (the W and Z belong to 1984), and fundamentalism is out of fashion, in any case.

So will 1986 have a more exciting structure? Predictions being impossible, extrapolations must do instead. The spacecraft Giotto will get Halley's comet (being almost there), the US Congress will be petrified by the prospect of next November's elections, there will be a lot more nucleotide sequences and people will be rightly alarmed by the spread of AIDS, and the consequences thereof. More of that next year. □

UK research councils

Science council thinks ahead

BRITISH academic astronomers are seeking to persuade the Science and Engineering Research Council (SERC) to transfer the staffs of the two UK observatories to university research centres. So much has emerged in the past week, in advance of the publication of the SERC "corporate plan", published earlier this week. The plan says that one of the many questions

Expenditure on R&D as percentage of GDP 1981-83.

still unresolved about its future is that of the two observatories, the Royal Greenwich Observatory at Herstmonceux in Sussex and the Royal Observatory, Edinburgh, whose present functions are chiefly those of providing ground support for British telescopes at La Palma in the Canary Islands and on Hawaii.

Astronomers at the University of Cambridge advocate that SERC should establish a centre for astronomy in Cambridge to which a substantial part of the staff from Greenwich would be transferred. One of the other contenders is the University of Manchester, whose case is based on the commonality of interest between the radioastronomers of Jodrell Bank and those at Edinburgh concerned with the millimetre telescope on Hawaii.

These arguments will presumably be adjudicated by the committee under Sir John Kingman, chairman of SERC until last October, which is looking into the future of the two observatories.

The emergence of these proposals is an illustration of the difficulties faced by SERC in trying to match its future organization to its expected budget. Its plan is more a restatement of familiar problems than a resolution of them.

The starting point is the council's statement that its work is at present limited by the shortage of funds, with the result that many good projects cannot be supported. SERC on this occasion points to increasing competition in basic research not only "by the USA and Japan, but by France and Germany". The plan argues that science has "an exponential dynamic", implying that discovery creates new needs, and says that external constraints on its operations at present are "too severe".

For the immediate future, SERC says

that it hopes by 1989 to release an extra £18 million a year from its own resources. The most urgent use of the funds, the plan says, is for the direct support of universities. As well as seeking a reduced subscription to the CERN laboratory at Geneva, SERC intends to reduce spending on support for high-energy physics by a fifth. On space research, the council says that it will concentrate its support for the European Space Agency on projects in basic research, and that its intended participation in the British National Space Centre will not persuade it, "at least for

the time being", to increase spending

Among the other casualties of planning within restraint are the proposed upgrading of the tandem accelerator at Oxford. Ultimately, SERC says, it will also want to reduce its involvement in the Institute Laue - Langevin at Grenoble, although it hopes before then to have reached agreement with other European research councils for international participation in the Spallation Neutron Source at the Rutherford Appleton Laboratory in exchange for British participation in the European Synchrotron Radiation Facility. □

British research

A little more all round

SIR Keith Joseph, British Secretary of State for Education and Science, this week announced the science budget for the next financial year (see table). Sir Keith has accepted the advice of the Advisory Board for the Research Councils (ABRC), which each year tells the government how it thinks the money

Government expenditure on British research (£ million)

	1985-86	1986-87	Increase (per cent)
AFRC	50.3	52.7	4.7
ESRC	23.6	23.6	0
MRC	122.3	128.3	4.9
NERC	67.3	70.3	4.5
SERC	298.0	315.5	5.9
British Museum (Natural History)	16.2	17.2	6.2
Royal Society	5.9	6.4	8.5
Others		0.6	
Total for 1986-87		614.6	

should be divided. The only part of ABRC's advice that Sir Keith rejected was that the Department of Health and Social Security should bear the full costs of establishing a centre for coordinating epidemiological research on acquired immune deficiency syndrome (AIDS). Although the health department may pay up to £0.3 million to the centre, Sir Keith has firmly told the Medical Research Council (MRC) to meet the balance of the costs of the centre from its allocation.

The total science budget for 1986-87 includes an extra £15 million that Sir Keith pulled out of his hat last month. ABRC has recommended, and Sir Keith agreed, that of the new money, the Agricultural and Food Research Council (AFRC) should receive £2.5 million for "new initiatives in its institutes", MRC £2.5 million for research grants and programmes, the Natural Environment Research Council

(NERC) £1.9 million, the Science and Engineering Research Council (SERC) £6 million to support "strategic research of industrial relevance" and the rest will enhance ABRC's "flexibility margin".

ABRC intends to produce a strategy document next year to take account of the corporate plans of each research council (see above). It will also change its normal schedule so that it will consider both the overall financial position of the science budget and the relative positions and claims of the individual research bodies in one exercise in March 1986.

The only body not to receive an increase in funds for 1986-87 in Sir Keith's statement is the Economic and Social Research Council (ESRC). The council is unlikely to be too distressed at the news; this is the first time in four years that its budget has not been cut. ESRC has taken seriously its brief from ABRC to toughen up; last month it took the controversial decision to blacklist any institution in which ten per cent of research students failed to submit a thesis within four years, and deny them the right to apply for any more grants for two years. Fourteen such institutions were blacklisted and given until last week to appeal. ESRC has now considered those appeals, and this week announced that five institutions have been reinstated for various reasons, including inaccurate statistics, failure to inform ESRC of withdrawal and two administrative errors.

Kings College London (KOC), Leeds Polytechnic, the University of London Institute of Education, University College of Wales (Swansea) and UMIST have gained reprieves. But Queen's University Belfast, the Universities of East Anglia, Liverpool, Aston and Dundee, Manchester Business School, Sheffield Polytechnic and Paisley College of Technology have failed to persuade ESRC to reverse its decision. Maxine Clarke

Strategic Defense Initiative

Congress questions UK pact

Washington

DESPITE high hopes in Europe that President Reagan's Strategic Defense Initiative (SDI) might lead to thousands of millions of dollars of SDI contracts for European scientists and engineers, the Europeans are unlikely to see much more than about \$300 million in total, according to congressional testimony last week by John Pike of the Federation of American Scientists, an unofficial pressure group. Pike's analysis, based on an examination of existing SDI contracts, identifies six major barriers to European cooperation and warns that the political repercussions due to failed expectations will reduce the already hesitant and patchy support for SDI in Europe.

SDI is expected to let contracts worth in total about \$30,000 million in the five years to 1990. But almost half of this will be off-limits to European countries because of articles and "agreed statements" in the Anti-Ballistic Missile (ABM) treaty of 1972, which prohibit transfer to other states of not only ABM systems and their components but also technical descriptions and blueprints specific to such systems. The US administration has repeatedly said that it is conducting SDI research in full compliance with the ABM treaty, and British support for SDI is conditional on continuing compliance.

Pike believes the treaty will prevent European participation in major SDI projects such as sensors, rocket interceptors and directed-energy weapons. Instead, participation would be restricted to basic research and development only of very small devices and subsystems, for which the dollar value would be "trivial".

Pike's second major impediment to cooperation is the limited capabilities of European companies, which in his view puts a further one-third of SDI beyond their reach. Pike pointed out that, in contrast to the very limited experience of European companies, the United States has spent \$50,000 million on ABM research over the past 30 years.

A twelve-year-old US defence procurement regulation prohibits contracting with foreign sources if a US source is equally competent and willing to do the work; exceptions appear to be allowed only if the foreign government concerned reimburses the US government for the work. The record so far is not encouraging: none of the 1,000 SDI contracts so far let have been to non-US companies (there is one small subcontract in Britain) and there were similarly no contracts for non-US companies among the \$3,000 million spent by the US Army on ballistic missile defence between 1975 and 1985.

Having disqualified non-US companies from \$24,000 million of SDI work on treaty and technical grounds, Pike went on to tell a subcommittee of the House of Re-

presentatives' Committee on Banking, Finance and Urban affairs that a further \$5,000 million was excluded because its commercial potential would mean keeping it in the United States or because of inherent geographical restrictions. Of the \$1,000 million left over that would be available for foreign competition, Pike estimated that a maximum of 30 per cent is likely actually to go overseas.

The hearing was held shortly after the announcement of the signing of a memorandum of understanding between Britain and the United States on SDI. As the terms have not been made public, the likely effect of the agreement is hard to gauge. But Representative John LaFalce (Democrat, New York) told Dr Gerold Yonas, chief scientist of SDI Organization, that he believed the purpose of the US administration in obtaining the agree-

ment with the British was political in that it was expected to foster European political goodwill. LaFalce warned that the United States might "build itself up for a fall" if the agreement created false hopes.

Concern about the effect of the agreement on US employment and the economy was evident in aggressive questioning of Yonas by Representative Bruce Vento (Democrat, Minnesota). Vento repeatedly asked how there could be open competition for research contracts if even a non-specific commitment had been made to support research in Britain. LaFalce questioned whether the United States should be entering agreements that might mean US taxpayers' money generating commercial spin-offs to benefit Europe. Questions were also asked about the confidence the administration had that classified material would be kept secret in Britain. Yonas replied that one of the purposes of the intergovernmental agreement was to control classified information centrally.

European military technology

France veers towards integration

THE US Strategic Defense Initiative (SDI) is an imperfect shield in response to which the Soviet Union need only "sharpen its foil", French scientists claimed this month at the second open "science and defence" meeting organized by the French government.

But the canny French do not ignore the implications of the US programme. Did they not launch the Eureka programme of European collaboration in high-technology products in response to SDI? Last week, M. Roland Dumas, the French foreign minister, said that Europe should now also pay attention to the development of a military counterpart to Eureka. Dumas thus mildly echoed the somewhat stronger proposal a week before of the previous President of France, Valéry Giscard d'Estaing, that Europe needs not only a military Eureka, but its very own "star wars" shield.

Dumas did not go so far. Nor did the other participants in the meeting, held at the Ministry of Defence's own grande école, the École Polytechnique. The technical aspects of SDI were thoroughly rehearsed — a defensive satellite system

would need twenty times as many satellites as could be used to repel an attack, 95 per cent of the system being likely to be out of range, while the Soviet Union could launch missiles in convoys to saturate this usable 5 per cent. The hardening of launchers, a reduction in the boost period, rotation of the vehicles and other measures could increase the power requirements of directed-energy weapons twentyfold, people argued. And cruise missiles deep in the atmosphere could avoid the system altogether.

Dumas said that SDI has nevertheless already achieved one thing — the "scattering" of Europeans, with each nation reacting differently to the challenge both technologically and politically, despite the counterbalancing effects of Eureka. There must in particular be an effort at cooperation in military technology within Europe, Dumas said, overlooking the recent commercial and diplomatic conflict between France and Britain over the supply of advanced battlefield communications technology to the US Army. Dumas went on to say that it is time "to provoke a political effort among governments . . . very soon in the coordination of military and industrial policy". Dumas was arguing, indeed, for a truly European "military/industrial complex" of the kind that has stimulated much basic and applied research in the United States and which, so far, is lacking in Europe. Strange again, perhaps, for the foreign minister of a Socialist government which in rosier days was arguing for the banning of nuclear tests and a curbing of the world arms trade, of which France is now the leader behind only the United States and the Soviet Union.

Robert Walgate

Japanese ethics

Edging towards transplants

Tokyo

HEART transplants are likely to begin in the near future in Japan following the preparation of a new definition of "brain death" by an advisory panel of the Ministry of Health and Welfare. Only one heart transplant has ever been carried out in Japan: that was 17 years ago and caused a major outcry, including demands that the doctor responsible be tried for murder. Similar demands for prosecution were again made this year when surgeons performed a combined liver and pancreas transplant operation at Tsukuba University.

One major factor that facilitates opposition to transplants is the lack of an officially recognized or widely accepted definition of "brain death". A patient who is brain dead has lost all brain activity and has no possibility of recovering. But the use of "artificial lungs" and drugs to maintain blood pressure can keep the patient breathing and his heart beating, often for periods of many weeks. Transplants of "living" hearts and lungs from these patients can save other people's lives.

Without continuous artificial respiration, a brain-dead patient's heart will stop very quickly; a patient whose brain stem still functions and who can breathe without artificial aid is a different matter. Whether or not the life of these latter patients can be legally terminated has recently been the focus of attention in the West. Brain death has, however, already been accepted as a legal criterion of death and has made transplants of heart and liver almost commonplace. Japan on the other hand is still a long way from accepting brain death as death of the person.

Until now, a set of criteria of brain death recommended by the Japanese Society of Electroencephalography has been in general use but each hospital has modified it as it sees it. There has been general reluctance to remove organs from brain-dead patients in order to conduct transplant operations; instead, patients have been maintained for weeks or months until the heart stops beating and the patient is recognized as legally dead. This has both inhibited the performance of transplant operations and tied up expensive medical facilities.

The new definition is considerably more straightforward than the earlier one. It was worked out by a panel of eight neurologists who examined the medical records of more than 700 cases of brain death. Five symptoms are now taken to define brain death: deep coma; loss of spontaneous breathing; enlargement of both pupils to more than 4 mm; the loss of reflexes governed by the brain stem; and flat brain waves, all lasting for at least six hours. Certain cases are excluded — those involving young children whose powers of recovery may be exceptional and those

caused by poisons.

Armed with the new definition, doctors will have a much clearer guide to the propriety of recognizing a patient as dead and the number of transplant operations is likely to increase. But the new definition is only a beginning and by no means clears away all obstacles to transplant operations. The ministry has no intention of taking the next step and preparing a new law that would recognize brain death as a legal definition of death. Doctors responsible for brain-dead patients will thus still be in an ambiguous position and acceptance by family members will be required before brain death can be agreed to constitute the death of an individual. The extent to which brain death is truly recognized and the facility with which transplants will be carried out will thus depend on how quickly brain death is accepted as "death" by ordinary citizens. At present, surveys show that less than a third of the population are ready to take this step.

One obstacle is a suspicion that doctors

are over-eager to perform transplants. Partly to allay such fears, two doctors on the advisory panel involved in transplant research resigned before its conclusions were released. It was thought that those known to favour transplants would not influence the panel's conclusions.

A separate difficulty lies in public attitudes towards organ donation. Despite figures that show that Japan has fewer believers in religion than any other non-communist country (if belief in some form of after-life or reincarnation can be taken as a definition of religion), there remains in Japan a peculiar resistance to donating organs. Even kidneys are in short supply, although transplants may be made from patients whose hearts have stopped beating. Quite why this is so, nobody is sure; commentators point to everything from the influences of Buddhism and Confucianism to a lack of public information campaigns (see *Nature* 313, 338; 1985).

Several competing hospital groups are known to be eager to boost their reputations by performing the nation's "second" heart transplant, and the new report will certainly improve their chances of doing so without censure. **Alun Anderson**

Space telescope

Discretion dispute on viewing time

Washington

US ASTRONOMERS are divided over a proposal to give scientists at the Space Telescope Science Institute (STSI) preferential treatment in the competition for viewing time on the Hubble Space Telescope. The proposal would ensure that principal investigators at STSI got at least 5 per cent of viewing time by using some of the "director's discretionary time" set aside for maintenance, calibration and unforeseen "targets of opportunity".

The proposal has been formally presented by STSI staff to several space telescope advisory committees. The preferred option is that up to half of the director's discretionary time (which amounts in all to 10 per cent of observing time) would be used by STSI principal investigators who failed to win time in the open competition for observing time. Only as much discretionary time as necessary to bring STSI principal investigators up to 10 per cent of the total observing time would be allocated in this way.

Concern about the proposal has been expressed in a letter sent to Dr Lyman Spitzer Jr, chairman of the Space Telescope Institute Committee, and signed by Dr Jeffrey Linsky, chairman of the Astronomy and Relativity Management and Operations Working Group. The working group says the STSI proposal is contrary to the spirit of the initial agreement that led to the establishment of STSI. The letter goes on to acknowledge that the proposal would solve a morale problem at STSI but questions whether the suggested

figures adequately reflect the proportions of competent investigators at STSI and elsewhere. At many other national astronomy facilities, in-house scientists compete in the usual way and succeed in getting an adequate proportion of viewing time, from 15 to 40 per cent of what they ask for.

Linsky's committee also disputes that the proposal would not delay observations by other guest observers. It seems likely that some of the special capabilities of the telescope, for example the ability to track moving objects such as a detail on a planetary moon, will not be completely calibrated at launch, and all of the director's discretionary time may be needed for that purpose.

The reason cited by STSI to support preferential access is that it would be in the general interest of the project to ensure that some scientists at STSI are also observers. STSI argues that its scientists are at a disadvantage in the competition for viewing time because they are working flat out to complete STSI's data handling and control systems in time for a scheduled August 1986 launch and so have been unable to devote enough time to preparing observing proposals.

Dr Riccardo Giacconi, director of STSI, said that while STSI scientists nominally spend 50 per cent of their time on research, in practice many spend only 20 per cent. Giacconi said a system similar to that being proposed is used at Kitt Peak National Observatory. **Tim Beardsley**

Electron-beam lithography

How to make chips to order

Menlo Park, California

THE Stanford Research Institute (SRI) International, the commercial contract research institute, claims to have carried the technology of electron beam lithography to the point at which the technique can be used for making individual semiconductor microchips, not simply the masks used in semiconductor mass production. Those responsible say that the technique has hitherto been too slow to be used in mass production, where optical lithography remains the chief technique. But SRI will need a commercial partner — and millions of dollars — to commercialize its machine.

According to Dr Ivor Brodie, director of SRI's physical electronics laboratory, the growing demand for bespoke microchips, both in silicon and gallium arsenide, has helped to make electron beam lithography a commercial proposition. SRI is now looking forward to a market that could be worth \$1,000 million a year by 1992. Brodie says that the demand for bespoke chips was not foreseen. "People want a particular integrated circuit for a particular purpose, and do not want others to copy it", he says. Instead of relying on general-purpose devices programmed for particular functions, he says, "people are now doing the programs, as it were, by hard-wiring".

The SRI machine is certainly quick. A semiconductor wafer 200 mm in diameter, and typically carrying 1,200 separate chips, can be "written in about a minute", according to Brodie, who says that with existing electron beam machines, it takes between half an hour and an hour to "write" a mask of the same size.

The electron beams in the SRI design are fired from an electron gun, focused through a screen of lenses at zero volts to the wafer being processed, which is itself maintained at a higher voltage. The multiple beams can be switched off and on by adjusting the voltage. By the use of several beams, it is possible to etch an identical pattern on several different parts of a semiconductor wafer, thus allowing several identical integrated circuits to be created simultaneously.

NASA Lewis Research Center and the Naval Research Laboratories have led SRI to develop custom-made microchips that could miniaturize CRTs. Capp Spindt, senior research engineer leading the project, says that NASA's interest was originally inspired by the need for a source of high current density for its satellite communications. Thermionic emission on cathodes were inefficient, needing heat to excite electrons from an element into the vacuum to create the electron beam. SRI's approach is based on field emission techniques in which electrons are produced by tunnelling to the surface of the metal on which is induced a high

electric field. The process is efficient.

Using this foundation, SRI has developed microchips which produce very-high-current densities — more than 60 A cm⁻² to 100 A cm⁻² or about three times the current densities normally expected of thermionic emission. The design, says Spindt, is based on the well-tried methods adopted for years in the semiconductor industry — a sandwich of metal, silicon oxide and silicon (MOS).

Using electron beam lithography, the researchers were able to etch out the design creating a pattern of holes in the substrate into which they could insert a metal, the source of electron emission. "You have this metal film with a hole in it. You

have an insulator spacing it . . . and the ground plane silicon you can work from. And it's very closely spaced. Then we developed a technique for growing a very sharp point which rests on the silicon."

The distances between these holes are about 2 µm, giving densities of more than 1.2×10^6 tips per cm², and arrays with more than 10,000 tips have been fabricated. Very high current densities result when the device is electrically excited. The next stage in the development is to explore how the technique can be used to enhance the designs of displays. The high current densities are expected to make any CRT picture brighter — and therefore ideal where the environmental light is at a high level, as in a cockpit/flight-deck — and because of the compactness of the silicon, to reduce substantially the width of any display.

Bill Johnstone

Creationism

California sells out on textbooks

Washington

EVOLUTIONISTS in California were bitter last week about what they call a "sham" hearing held by the State Board of Education that approved revised biology textbooks for state schools despite "hundreds" of factual errors and weak coverage of evolution. Revisions made by the publishers to take account of criticisms by the state's curriculum commission introduced more errors than they eliminated, according to William Bennetta, who has been working for better treatment of evolution in textbooks.

The revisions were made after the curriculum commission recommended in September that the books, for twelve- and thirteen-year-olds, should not be accepted because of their avoidance of evolution and inadequate treatment of human reproduction and ethical questions. Publishers are anxious not to offend the strong US creationist lobby, which has threatened to sue in California over the

books now approved. California represents more than 10 per cent of the US textbook market.

A spokesman for the state board said that the books had been greatly improved by the revisions. Publishers had threatened that a failure to adopt the revised books last week would have made it impossible for books to be produced in time for the start of the academic year next September; because textbooks are adopted in California on a six-year cycle, a delay could have held up planned improvements to books in other subjects. Dr Bill Honig, state superintendent for public instruction, said he believed the books now to be the best in the country. A final review by a curriculum commission subcommittee would be able to eliminate any factual errors in the books that were identified at the hearing.

Bennetta and his supporters are not impressed with this promise, pointing out that the subcommittee has no biologist among its members. Most of the books were not altered extensively, as the evolutionists thought necessary, and even those that made significant changes avoided open acknowledgement that evolution is the received wisdom, often using such terms as "many scientists feel" as qualifiers.

The evolutionists complain that the revised books were deliberately made difficult to examine (one copy only was exhibited, for 12 working days, in the state capital) in order to minimize the risk that errors and weaknesses would be exposed. Bennetta's favourite example is in *Health Life Science*, published by Heath and Company, where a statement in the original version that "many scientists believe that dinosaurs were the ancestors of reptiles" has been replaced by the assertion that scientists classify dinosaurs as the ancestors of reptiles.

Tim Beardsley

Aleksandrov's fate?

ALMOST nine months after the disappearance of Soviet computer scientist Vladimir Aleksandrov in Spain, the Soviet Academy of Sciences last week said that he had disappeared without trace in Madrid on 1 April on his way home from an international conference of mayors of "nuclear-free" towns. Diplomatic representations had received "no clear reply". The academy did not explain why it had been officially silent for so long. But Soviet unwillingness to discuss the disappearance has, undoubtedly, fuelled rumours circulating in the West that Aleksandrov, co-author of the Soviet nuclear winter computer model, had been intending to defect, but was prevented by Soviet security men.

Vera Rich

French space

Will US Congress fill vacuum?

THE French space agency, CNES, plans to spend more on basic science, lifting the proportion of its funds from 6–7 per cent now to 10 per cent by 1990. But this is only a target, according to research director Isaac Revah last week. One of the imponderables is whether US participation in the joint Topex/Poseidon oceanographic satellite, France's biggest project so far in basic space science, will survive the automatic budget-cutting mechanisms to which the US government is now committed (see *Nature* 318, 495; 1985).

So CNES is hatching contingency plans for Poseidon, the French half of the project. British or Scandinavian participation is being mentioned as an alternative. But the possibility of collaboration with the Soviet Union, for which there are many

CNES precedents, is "certainly not" on. The Poseidon satellite instruments, consisting of a high-resolution altimeter, a troposphere radiometer and positioning equipment capable of fixing orbital positions to within 10–15 cm, have an obvious military interest.

The US half of the project, Topex, has also thrown up problems of secrecy. The purpose of these instruments is to infer ocean currents from measurements of ocean topography. Nominally, the project is a civil enterprise. But the US Department of Defense has slapped restrictions on the details of the instrumentation. France, through CNES, has retaliated by offering the United States only black-box descriptions of what the Poseidon instruments will do. If the US National Aero-

navics and Space Administration (NASA) fails to get its money, Poseidon will be flown on a French Earth observation satellite, one of the SPOT series, in 1990–91. "We don't need technology transfer in this field", Revah says.

The French space programme for the next few decades, now becoming clear in its outlines, is diverse and ambitious. In basic science, according to Revah, more attention will be paid to Earth science, but not at the expense of astronomy, supported mainly through agreements with the Soviet Union. On the hardware side, France is committed to the development of the Hermes space shuttle, the cryogenic third stage of Ariane, and participation in the European contribution to the US space station, the separate vehicle called Columbus.

For the rest, the following projects and programmes are on the cards.

- A satellite called Magnolia for precise measurement of the Earth's magnetic field, possibly to be built before 1995. (A similar project for the measurement of gravitational fields, called Gradio, has encountered technical snags and may be put back.) Beyond that, CNES prefers to talk of programmes rather than particular satellites, but there is an inclination to concentrate on measurements that will help to define the hydrological cycle in the troposphere, with obvious applications in climatology. By 1995, the officials say, it may also be possible to make direct measurements of the ground motions expected from plate tectonics and at geological faults, either by the comparison of successive high-resolution photographs or with the help of fixed ground beacons.

- In astronomy, priority will probably be given to Franco-Soviet collaboration on Vesta, a mission to Venus and the asteroids, that will cost France FF600 million. But there is a host of other projects, suggested by the French community, competing for CNES funds. These include a low orbiter for the study of the internal structure of Jupiter, a Mars rover that would look for traces of water, a radio-interferometer called Trio and participation in the proposed European Space Agency (ESA) high-resolution spectrographic X-ray telescope. The only certainty is that CNES will not be able to support all these projects.

- On manned spaceflight, CNES hopes to arrange a long-duration space flight with the Soviet Union so as to engage the French space medicine community; as always, it is looking for industrial interest in the exploitation of microgravity environments.

This year, French spending on these activities will have amounted to FF150 million in bilateral programmes, almost entirely on instrumentation, plus FF200 million on the ESA science budget. This makes a total of FF350 million, compared with the goal for 1990 of FF600 million.

Robert Walgate

Soviet science

Making policy by TV camera

A REMARKABLE innovation in television programming, allowing public questioning of Soviet government officials, seems to have been part of the preparation for the Soviet Union's 27th Party Congress in February. On 29 November, Soviet television stations broadcast a phone-in with viewers' questions about "accelerating scientific and technical progress", a keynote phrase of all Soviet economic documents of the past decade.

The panel included Academician Anatolii P. Aleksandrov, president of the Soviet Academy of Sciences, two vice-presidents of the academy (Evgenii P. Velikhov and Yuri A. Ovchinnikov), two deputy prime ministers (Ivan S. Silaev and Guri I. Marchuk) and the chairman of the State Committee for Discoveries and Inventions, Ivan S. Nayashkov. The producers seem to have created an atmosphere of spontaneity, but since it had also been possible to telephone questions in advance, and since the questioners' voices were never heard, it is impossible to know how many replies were genuinely unprepared.

Nevertheless, the programme does seem to have reflected genuine public criticism and doubts. Here are summaries of some of the exchanges:

Q: Why are the power sets of the Leningrad, Ignalina and Chornobyl nuclear power stations built in five different — and flawed — designs?

A: We're working on it.

Q: Why does it take more than 12 years for a "practical invention" to be introduced into the economy?

A: It takes only six years, and we are trying to reduce this time.

Q: What are personal computers, and won't they make people "unlearn" how to count? (This question was from a school-

boy, presumably too young to have started the new compulsory computer studies course.)

A: On the contrary, they expand the human capacity for thought.

Q: What is being done to overcome "high-handed administration" and "the cult of the director" in certain scientific establishments?

A: The powers of directors are now being widened, but we have the means to counteract the negative features of high-handed administration.

Some questions, however, seem to have been specially picked to allow the panel to expatiate on new plans and proposals — the concentration in the new Five-Year Plan on machine tools, the establishment of biotechnology centres in rural areas or of a laboratory to monitor how the young generation in schools accept computer technology, and "whether it will do any harm to their development".

A question to Academician Ovchinnikov in his role as chairman of the All-Union Society for the Struggle for Sobriety itself answered one question that has been puzzling many Soviet citizens, not to mention Soviet-watchers abroad — why have scientists in particular been coopted in such force into the anti-alcohol movement?

Ovchinnikov's answer is that the acceleration of scientific and technical progress requires increased labour discipline, that is, the elimination of drunkenness. Ovchinnikov, himself, it appears, is in favour of total abstinence.

Other questions related to recent policy decisions such as the merging of the medical and microbiological industries, and the commitment to thermonuclear power emphasized at the Geneva summit.

Vera Rich

British research

Catalogue of steady decline

ALTHOUGH declining British government support for civil research is offset by an increase in support for military research, this has not prevented a decline both of the proportion of the Gross Domestic Product (GDP) spent on research and of Britain's standing relative to other industrial nations in civil research spending. This is the simplest lesson to be drawn from the *Annual review of government funded R & D 1985*, published earlier this week (HMSO, £9.50).

The survey is the fourth in the series produced since the House of Lords Select Committee on Science and Technology recommended in 1981 that there should be such a document. It is also the last to be produced by Sir Robin Nicholson, the scientist member of the Cabinet Office who will be leaving in the new year to become research director of Pilkingtons, the glass manufacturers.

Nicholson obviously hopes that he established a tradition that will survive not only his office but general elections yet to come, explaining how future editions will improve on the quality of the data (which is at present variable, especially on topics such as manpower). One guarantor of survival is that the survey is entirely free of value judgements, and that government departments' own estimates of their research spending under various categories are normally entered as supplied.

The survey is largely based on figures for spending by government departments covering the last financial year (to last April) together with the three immediately previous years and plans for the present and the two succeeding years (as announced last February). The figures, such as they are, for industrial spending on research and development come from a survey carried out by the Department of Trade and Industry.

In the current year, according to the survey, government spending on research and development is at a shallow peak, amounting in real terms (and 1983-84 prices) to £4,137 million. On present plans, the total is expected to decline from now on, to £3,966 million in 1987-88. Within this total, however, defence spending on research and development, now just over a half at £2,077 million, is expected to increase modestly to £2,181 million in 1987-88 (again at 1983-84 prices). But even these figures make the conventional but increasingly doubtful assumption that about 30 per cent of spending on higher education may be counted as research expenditure.

Nicholson emphasized earlier this week that the international comparisons suggested by the survey are made uncertain by the extent to which the data cannot easily be compared. But according to data collected by the Organisation for Econo-

mic Cooperation and Development (OECD), Britain stands out as the only major member country in which total spending on research and development (by industry as well as government) has actually declined in recent years (by 0.9 per cent in 1983, the latest year for which a comparison is attempted). □

US panel split on guidelines

Washington

AGREEMENT was finally reached on 4 December on policy guidelines for the safe introduction of recombinant DNA technology by a working group of the Organisation for Economic Cooperation and Development (OECD). The guidelines have now only to be formally approved by OECD's Committee on Science and Technology Policy before being published.

The drawing up of the guidelines, which has taken two years, spawned dissent between US agencies which led to the cancellation of a meeting of the working group in August and expressions of concern by US senators. At the meeting earlier this month at OECD's headquarters in Paris, the US delegation offered a radically changed version which omitted a section of a previous draft dealing with large-scale industrial practices. The compromise document now agreed represents "a merger of the best of both versions", according to Dr Frank Young, commissioner of the US Food and Drug Administration (FDA), who secured the eventual agreement between US agencies. Dr Henry Miller of FDA, whose involvement in the project generated controversy, said he was "absolutely delighted" with the results.

The confusion over the US position delayed completion of the guidelines by 4-6 months. The representative of the Environmental Protection Agency who earlier coordinated US work on the project boycotted the latest meeting.

The document now agreed endorses the use of agreed standards of good industrial large-scale practice for genetically engineered organisms deemed to represent a low risk; many OECD countries had been waiting for this recommendation to cite as justification for their domestic policies. Higher-risk organisms can be safely handled with established containment techniques. When considering environmental releases of genetically altered organisms, the document says risks can be evaluated in the same way as for other organisms, and recommends a step-by-step approach of progressively expanding the containment through small-scale and then large-scale field tests before allowing full release.

Tim Beardsley

Deep-sea drilling

Britain rejoins programme

A BLACK sheep became a prodigal son last week, when the British Natural Environment Research Council (NERC) announced that it would be able to find the annual subscription for the new Ocean Drilling Program being organized by the National Science Foundation in the United States through the intermediary of JOIDES, the consortium of US oceanographic institutions responsible for the earlier IPOD (international phase of ocean drilling) programme. Britain participated in the planning of ODP, but did not become a full member because NERC could not pay the \$2.5 million annual subscription.

Signs that the prospects were good were seen last month, when the secretary of the council, Dr John Bowman, said that he hoped to have raised the subscription for 1986 by the end of the year. Now, it seems, the Department of Energy and other government departments have agreed to meet a fifth of the cost, with the oil companies providing 14 per cent. NERC will provide the remainder, equivalent to about £1.2 million at present exchange rates and will also stand the risk of future currency fluctuations.

Everybody seems cheerful about the prospect. At a meeting of the British coordinating committee last Friday, Dr Tim Francis of the Institute of Oceanographic Sciences was appointed as the British representative on the ODP planning committee, next due to meet at the end of January in Hawaii.

Representatives were also nominated for the dozen or so working groups of ODP, now mostly organized on regional lines, but it may be necessary to change these assignments, if, as seems likely, the structure of ODP is recast.

Even so, Britain will participate only in Leg 107 of the new programme, which is planned to sail from Malaga for several drilling programmes in the Mediterranean on 26 December next year. (The first leg of the new programme will put to sea on 31 January 1986.) There is particular British interest in Leg 14, in the Weddell Sea, in the Antarctic near the British station to be drilled in 1987.

Domestically, the British coordinating committee under Professor M.G. Audley-Charles (University College, London) will expect the British representatives on the ODP working panels to act as convenors of parallel groups among British geophysicists. The presence of the oil companies among the sponsors of the British contribution is reckoned to have been politically if not financially crucial, given the British government's belief that industrial sponsorship of research is a public good in itself. □

Japanese energy

Go-go go for nuclear power

Tokyo

JAPAN's white paper on nuclear power released this week is full of the boundless enthusiasm for nuclear energy that seems to have evaporated in the West. The call is for more nuclear power stations, the rapid development of an independent capacity to process and enrich nuclear fuel and increased effort to develop fast-breeder reactors.

The logic is simple enough. At present, nuclear power stations provide Japan with its cheapest source of electricity. According to the report, this year nuclear-generated electricity cost 13 yen (\$0.6) per kwh, against coal-generated electricity at ¥14 per kwh and liquid natural gas generated electricity at ¥17 per kwh.

The calculation for nuclear energy does not, however, include the price of decommissioning old nuclear reactors; adding this in gives nuclear power just a very slight edge over coal. Thirty-one nuclear reactors in Japan are between them supplying 23 per cent of the total electric power. That places Japan fourth after the United States, France and the Soviet Union in its total nuclear power generating capacity.

Japan's situation is, however, unique, for the nation has almost no fossil fuel reserves and must import 90 per cent of its energy, much more than any other large industrialized country. In the report's view, the cost of those fossil fuels is bound to rise over the next decade and the advantages of nuclear power become ever more apparent, although oil prices are now falling as the OPEC nations try to boost sales.

The key to Japan's cheap nuclear power is operating efficiencies that are the highest in the world. As nuclear fuel costs are small, the price of nuclear-generated electricity stems from the cost of plant construction and running and thus the percentage of time for which it is in operation. In Japan, power generation is suspended fewer than 0.1 times per year per reactor, just a tenth of the frequency of reactor troubles in the United States and attributed by plant operators to the superior training and conscientiousness of Japanese staff.

Enthusiasm for nuclear power seems to be shared by citizens too, most of whom, according to a government survey, think more electricity should be nuclear generated. Indeed, nuclear power seems to have a rather good image; when those surveyed were asked to list the uses of nuclear power, treatment of cancer was listed second after power generation.

As a government document providing a source of information for decision makers, the white paper might perhaps have painted a slightly less rosy picture. One proud boast of the government is that since commercial reactors began operation in 1966, "there have been no accidents or

failures in which operators or people living nearby were affected by radiation". That, strictly speaking, is true, but it avoids mention of the leaks on board the nuclear ship *Mutsu* and the 1981 leakage of radioactive water from a storage tank into the sea. Nor will its simple description of fast-breeder reactors as the mainstream power source of the future "fundamentally solving the problem of nuclear fuel sources" appeal to many, including those in Japan, who have tried to estimate the likely economics of these reactors.

Alun Anderson

Polish science

Congress delay

THE third congress of Polish science, scheduled for 9–10 December, has been postponed until March 1986, due to the "need for more thorough preparation of the plenary reports and also the papers being completed by the 16 problem teams". The purpose of the congress had been to review Polish science with special reference to the research applications in the economy.

The old hierarchy of graded levels of priority for research problems from "government" and "key" problems down to "departmental" problems, introduced after the second congress in 1973, has proved unworkable; some new research structure is clearly necessary. But it is apparently proving difficult to devise a viable alternative.

The first congress of Polish science (June 1951) served not only to assess the state of science but also to impose a rigidly Marxist philosophy on Polish research and learning. There are widespread fears (particularly after last month's dismissals of university administrators) that the forthcoming third congress might launch a similar purge.

Although the official reports for the congress may not be ready, one unofficial report has already appeared in the underground press. This is a 10,000 word pamphlet from the unofficial "Social Commission for Learning", which attempts to outline the effect of the crisis and martial law on Polish science and learning, including the "reorganization" of the Institute of Nuclear Research, the run-down of investment in science, the cessation of doctoral research in the universities in 1982 (it has only partially been restored), and in particular, the situation in the 200 or so research institutes responsible to some ministry or government department rather than to universities or the academy.

The pamphlet, although written in a detached and academic manner, gives a depressing picture of Polish science.

AIDS

Pasteur sues over patent

Washington

THE Institut Pasteur in Paris has filed suit in the US claims court in Washington DC, contending that researchers at the US National Cancer Institute (NCI) used Pasteur's specimens and data to develop and patent a commercial test to detect antibodies to the AIDS (acquired immune deficiency syndrome) virus. The suit asks the court to declare that Pasteur researchers Luc Montagnier, Jean-Claude Chermann and François Barre-Sinoussi were the first to isolate the AIDS virus and to recognize its significance in developing blood tests for AIDS antibodies.

Institut Pasteur researchers were the first to publish an initial characterization of the AIDS virus and filed a patent application for a test in December 1983; the application remains pending. The NCI researchers, led by Robert Gallo, filed a similar application in April 1984 and received a patent 13 months later.

Montagnier has claimed that he sent his viral isolate to Gallo as a scientific courtesy for research purposes in July and September 1983. But Gallo says the rate of production of virus in the cultures he received made them useless practically, and that development of a test and reliable characterization of the virus was impossible until his laboratory found a cell line that could produce the virus in quantity.

Montagnier's original isolate has subsequently been found to be very similar to Gallo's, but Gallo angrily rejects suggestions that his isolate was in any way derived from Montagnier's. Gallo says other isolates have been found that are both more and less similar to Montagnier's than his original, and that the similarity is nothing more than might be expected given that both originated from patients in New York City.

Gallo's patent, which was turned over to the US government, forms the basis of the tests currently in use in the United States for AIDS antibodies. The commercial value of the patent is counted in millions of dollars.

Other tests are expected to enter the market shortly that are derived from the Pasteur isolates, and one manufacturer, Genetic Systems, has said it will not be paying royalties on its test to the US government.

Pasteur had been negotiating unsuccessfully with the US government for the past four months to reach a compromise agreement on royalties from existing tests, which it believes should be shared equally between the US and French institutes (see *Nature* 317, 373; 1985). It appears that the question will now be settled in court: no date for a hearing has yet been fixed.

Tim Beardsley

The cause of university education

SIR—The way in which the political ideology of a democratic government can make or mar the cause of higher education or university autonomy is best illustrated in the action of the governments of France (*Nature* 315, 172–173 & 316, 5; 1985) and Britain (*Nature* 315, 265; 1985). In France, the present government has succeeded in freeing the universities from the overbureaucratization of higher education. The granting of absolute independence to the Comité National d'Évaluation des Universités (CNEU) so that it can make an objective evaluation of a university is a step in the right direction. This may free the university from day to day interference from political or bureaucratic authority. Furthermore, CNEU wants to lay equal emphasis on research and on teaching by individuals and groups within a university. This is most certainly a radical change from current practices in French universities, where too much emphasis has been laid either on research or on teaching in granting promotion to a member of the faculty. Promotion has depended on an individual's local political influence over the central machinery responsible for promotion.

The trend in British higher education has been the opposite. The present British government has inflicted maximum damage on the cause of university autonomy, of which the British have always been proud. Much has been written on the subject in editorials in *Nature* during the past two years. *Nature* has highlighted in a systematic manner the callous disregard of the present government for the sanctity of higher education. In this connection, the address delivered by Lord Attlee on the occasion of conferment of the Honorary Degree of Doctor of Laws by the University of Glasgow in 1951 is worth quoting:

"It has always been one of our proud boasts that our universities are free and are rightly jealous of any attempt by the State to extend its power over them. The administration by the University Grants Committee is a characteristic British device which while it passes muster with the financial critics of the House of Commons, leaves the universities almost complete freedom to run their own affairs. In a democracy it is fundamental that thought should be free and that the inquiring and critical university spirit should be brought to bear on all affairs. The University must ever seek for the truth; it must never be a mere instrument in the hands of a government, a church or any political or economic group."

The respect in which the universities of Great Britain are held is mainly due to the freedom from governmental interference that they enjoy (or used to enjoy before the onslaught initiated by the present government), both constitutionally and actually.

In this crisis, the low-key position adopted by the university community is worrying. British academic institutions have almost surrendered to the political

authority in its attempt to remove the autonomy of the universities. To free us from every kind of domination except that of reason is education in the real sense. This aim can be best achieved in an atmosphere of professional integrity where teachers are as free to speak on controversial issues as any other citizen of a free society. In Cardinal Newman's words, "A university education gives a man a clear conscious view of his own opinions and judgements, a truth in developing them, an eloquence in expressing them and a force in urging them".

Greenhouse dilemma

SIR—The background to the "greenhouse effect" is well-known. Carbon dioxide from burning fossil fuels, deforestation and cement manufacture causes global temperature to increase by about 3°C each time the proportion of the gas in the atmosphere doubles. At the current rate of manmade CO₂ production, the proportion will have doubled in about 230 years.

At the end of the last ice age, the global temperature increased naturally by only about 6°C with a corresponding sea-level rise of about 100 metres from melting ice in the following 2,000 years or so. By analogy, this implies a sea-level rise due to the greenhouse effect of at least 12 metres in the next 230 years with a further 38 metres still to come, even if the rate of CO₂ increase remains constant and there is no further rise thereafter. However, there is a close link between atmospheric CO₂ increase and population size.

It seems inevitable, therefore, that the greenhouse effect will induce sea-level rises high enough to drown many if not most major cities of the world and much of their agricultural hinterlands within the lifetime of the sea defences presently designed at massive cost to protect them. Alternatively, the population size might be contained and then reduced to decrease manmade CO₂ production. This would destroy the pensions and insurance structures of the developed world and family provision for the elderly of developing nations.

We appear to face a dilemma. Social structures will not allow us to reduce the population. Current technology and economics will not provide a workable alternative to the consequent continuing generation of CO₂ with its associated sea-level rise and massive incursions.

If we accept the greenhouse calculations, should we not be embracing their conclusions more urgently in the planning of relevant engineering and financial structures? On the other hand, if we choose to disbelieve the warnings, why are we paying dearly for them with public money?

BRUCE DENNESS

Metric system

SIR—Having grown up in the United States and lived in Britain, as well as visiting and living in several metric lands, I think A.A. Berezin (*Nature* 317, 762; 1985) has missed the point of D.C. Jolly's rather sensible letter on the metric system. A measurement system must first of all be a means by which one can orient oneself to the physical world. Any system satisfying this condition is, in that sense, as adequate as any other. I do not need to know how many square feet there are in an acre; I do need to know that an acre is a generous lot for a house but insufficient land to farm. A mile does not mean 5,280 feet to me. It means a long walk or a short drive. In my laboratory, I use the metric system exclusively, not because I believe it necessarily better but because it is the means by which I was trained to orient myself on scientific matters. When I do a physical examination of a patient, I measure and weigh in metric but report the results to the anxious human in feet and pounds. If Berezin ever told an American mother her baby had a temperature of 37 degrees, he would quickly understand my meaning. For myself as well, centigrade provides too narrow a gauge to describe bodily comfort compared to Fahrenheit, and also a fever of 104°F has a zing to it that 40°C could never match. The comforting security in tradition can sometimes more than compensate for the inconvenience of technical inefficiency.

Being universal, science needs a universal idiom and if that mandates metric, so be it. But how one sees one's personal world and describes it to others is quite another matter. For those purposes, the British-American system of measurements suits me and millions more just fine. What divides nations and peoples is not how they measure things but intolerance for the ways of others.

Calculating the orbits of comets

The return of Halley's comet may have been a disappointment, but new-found skill at calculating cometary orbits may help towards an understanding of these objects.

THE covert return of Halley's comet has been a great public frustration that may yet send hordes of people scurrying off to the South Pacific in March and April, after the perihelion passage predicted for 9 February 1986, just six weeks from now. In reality, the likelihood that very few people would ever see the comet was well signalled in advance; the Earth is on the wrong side of its orbit to make Halley the spectacular object it seems to have been in 1066 and 1682. At a perihelion distance of 0.59 astronomical units, there can be a tenfold variation in the apparent brightness of the comet with the position of the Earth. At this unfavourable passage, many people will have to be content with reading about the event, in which case they might do worse than browse through the proceedings of last year's International Astronomical Union symposium on the dynamics of comets, which have now been published*.

Comets have an obviously special place in planetary dynamics as naturally occurring test particles in attempts at the solution of the many-body problem in celestial mechanics. Unlike the other objects in the Solar System whose mass is negligible compared with that of planets, they have the particular advantage of moving in orbits that are often far from being circular. Given the interest in spacecraft orbits and the availability of computer power, not to mention the inherent interest of the subject (and even of Halley's comet), it is inevitable that people should have been so busily calculating cometary orbits.

But is that not simply a matter of solving a few differential equations? There are two practical snags. Comets are not ideal test particles, but self-accelerating objects as a consequence of the way in which they lose mass asymmetrically near perihelion. And even the best-known, among which Halley and Encke (found at the end of the eighteenth century) stand out, travel in orbits whose elements are poorly known, at least in comparison with the orbits of the planets.

Running through last year's symposium seems to have been a hymn of gratitude to B.G. Marsden from the Harvard-Smithsonian Institute of Astrophysics for his compilation over many years of an authoritative list of the orbital elements of more than a hundred periodic comets and for having, during the past two decades, founded the small but flourishing school of those who would put the treatment of

the "non-gravitational" influences on cometary orbits on a rational basis.

What began as an empirical attempt to calculate the acceleration (sometimes the deceleration) of the comet from the changes in its orbit, so as to learn something of the physics of the processes responsible, has been rationalized by supposing extra forces which are functions of the heliocentric distance. On this view, comets accelerate by the transfer of momentum from the escaping gases; for the case of Encke, Y.V. Batrakov and Y.A. Chernetenko from the Institute of Theoretical Astronomy at Leningrad now think that the non-gravitational forces can be related to the magnetic index of solar activity, which makes sense.

In practice, the outcome of these calculations seems as satisfactory as could be expected. The assumption that the non-gravitational force on a comet near perihelion is simply a function of the heliocentric distance and, specifically, that it is a power law works well enough. But the idea that the force could be in any direction than that towards the Sun requires that the nucleus of the comet should be spinning, whence the hope that the Giotto encounter next March may directly throw light on the revolution of the Halley nucleus.

Even without these qualifications, the solution of the differential equations of the motion of a comet is far from being simple. One obvious difficulty is that even the comets with very short periods are known accurately only from their brief passage through perihelion, so that integration entails projecting a set of non-linear equations forward for the equivalent of many years from a poorly known starting point. So far as can be told from last year's meeting, computers have made possible several new ways of tackling the problem, which is why it is (or should be) all the more humbling that, at the very beginning of the eighteenth century, Halley had applied methods to the calculation of twenty cometary orbits and that, by the middle of the century, A.C. Clairaut had been able to allow for the effects of Saturn and Jupiter on the orbit of Halley's comet so as to predict its passage in 1757 to within a month.

The neatest, or at least the most ambitious of all the programmes of calculation described last year, is that which yields comet orbits as by-products of a continuing international project to calculate

the evolution of the Solar System as a whole, known as the Long-Term Evolution Project. The project has the virtue of involving not merely people from Western Europe (among whom Italians are prominent), but also at least one group from Czechoslovakia. The objective is that the motion of the principal objects of the Solar System should be calculated almost from first principles. As with other numerical schemes of this kind, among which that of Edgar Everhart from the University of Denver is the best known, the proof of the pudding consists not of the agreement between predictions and future observations, but of agreement between the calculations and past records of the passage of known comets — "postdiction" as it is anachronistically called.

Many of the results really are quite startling, familiar though they may be to those working in the field. Even Halley is not as well-behaved as might be thought. D.K. Yeomans of the Jet Propulsion Laboratory describes the attempts made since Halley's own work in 1705, including that of Bessel in the early nineteenth century and of those this century who have had the benefit of the ancient Chinese records, only to conclude that this long series of perihelia, if used as the basis of strictly dynamical interpolation, foreshortens each cycle of roughly 76 years by about four days. With the discrepancy explained by the transfer of momentum at evaporation of the surface material, Yeomans concludes that the orbit of Halley's comet can have changed only slowly during the past 18,000 years or so, but that there may have been some more profound interaction with Jupiter at some point.

This fits in well with the calculations made of the behaviour of other comets in the past. There is for example, the case of the comet Oterma, whose orbit lies between those of Jupiter and Saturn, which encountered Saturn in the late eighteenth century, which has just spent two decades as a distant satellite of Jupiter, but which is now likely to return to much what its former orbit was. This is one of many examples quoted at the symposium to illustrate how comets filter their way from the supposed Oort cloud of comets-in-waiting, at some distance beyond Neptune, by successive encounters with planets into the inner Solar System. The comets we see are the exceptions.

Membrane proteins

Structure of a bacterial photosynthetic reaction centre

from Richard Henderson

ON PAGE 618 of this issue J. Deisenhofer *et al.* report the first structure at atomic resolution of a protein — or, more accurately, a complex of several proteins — from a biological membrane. Not only is it a superb structure but since it is of a photosynthetic reaction centre complex (from the purple bacterium, *Rhodospseudomonas viridis*), the result provides a structural basis for understanding photosynthesis. In addition, the work bears witness to the tremendous and continuously growing power of protein crystallography.

A great handicap in understanding any of the vital processes carried out by membrane proteins has been the lack of atomic structures for such proteins. The major problem is to release the proteins in undamaged and stable form from the lipid bilayers that constitute the membranes. There is no such problem with the water-soluble cytoplasmic proteins, 200 or so of which have had their structures solved. Ironically, since water-soluble proteins need a non-polar interior and a polar surface whereas lipid-soluble proteins could be largely hydrophobic and their internal hydrogen bonds would not have to compete with the hydrogen-bonding potential of the surrounding water, the architecture of membrane proteins might actually be simpler than that of cytoplasmic proteins.

It was over three years ago that Hartmut Michel produced large well-ordered crystals on the *Rps. viridis* reaction-centre complex using a method somewhat similar to those used to crystallize many water-soluble proteins, but based on a thorough understanding of the behaviour of the protein-detergent complex in the presence of small amphiphiles and of the precipitant, 2.5 M ammonium sulphate (*J. molec. Biol.* **158**, 567; 1982). There then began a fruitful collaboration between Michel and one of the most productive protein-structure groups in the world, headed by R. Huber. The crystals turned out to contain only one molecule of the complex per asymmetric unit, surrounded by solvent that fills more than 70 per cent of the crystal volume. After collection in a darkened cold room of X-ray diffraction data from the native protein and several carefully selected heavy-atom derivatives, an initial map of the structure at 3 Å resolution was obtained in which the chromophores were immediately identifiable (Deisenhofer, J. *et al. J. molec. Biol.* **180**, 385; 1984).

Further interpretation of the electron-density map has now allowed all the components of the photochemical reaction centre to be precisely located. The centre

contains four molecules of bacteriochlorophyll-b (BChl), two of bacteriopheophytin-b (BPh), two different quinones, a non-haem iron and four haems, all embedded in a protein that is made up of four polypeptide subunits containing a total of 1,187 amino-acid residues. The crystallographic unit cell of the reaction centre is smaller than that of the icosahedral viruses whose structures have re-

Schematic diagram illustrating a cross-section through the photosynthetic reaction centre of *Rp. viridis* showing the relationship between the 11 trans-membrane helices (5 of subunit M, 5 of L and 1 of H) and the region occupied by the chromophores, which is shown shaded. The helices are all tilted by angles of up to 38° to the direction of view, which is from the periplasmic side. They are therefore much closer together at the cytoplasmic side of the membrane and much further apart at the periplasmic surface than shown here, which is at a level close to the centre of the membrane.

cently been solved (see Harrison, S.C. *Nature News and Views* **317**, 382; 1985), but unlike them it is devoid of symmetry. It is the largest and most complex atomic structure yet determined. It is even more remarkable that the heart of bacterial photosynthesis, which is similar to photosystem II of green plants, should be the first membrane structure to be solved in detail.

Chromophores

All the chromophores in the complex have been precisely located. The quinone sites include both the strongly bound menaquinone (Q_A) which is found in the native structure, and the more weakly bound ubiquinone (Q_B), which was initially absent in the crystals and had to be located by the difference Fourier method after soaking the crystals in solutions of quinones and quinone analogues. The structure and function of the chromophores in the complex have been reviewed by J. Barber (*Nature News and Views* **315**, 278; 1985). All the chromophores except the haem groups of the

cytochrome are related in pairs by a local 2-fold axis which is perpendicular to the plane of the membrane. Thus on the periplasmic side of the membrane, a pair of BChl molecules are found in close contact with one another. They are called the 'special pair' ($BChl_2$), because spectroscopy has shown that they are in contact and that their oxidation is the primary event in photosynthesis.

Two alternative paths of electronically conducting chromophores extend from this special pair to the single non-haem iron atom which is positioned on the opposite (cytoplasmic) side of the membrane: each path consists of the sequence $BChl_2$ -BChl-BPhe- Q_A or Q_B -Fe. These chromophores accept excitation energy from light-collecting complexes of protein and chlorophyll and convert it rapidly into a charge separation across the full width of the membrane — approximately 40 Å. An electron is transferred from the (oxidized) $BChl_2$ to Q_B within 230 picoseconds, apparently always via Q_A which, after reduction, transfers an electron to Q_B , possibly via the non-haem iron. (It is not clear why electron transfer does not also proceed along the other pathway, directly to Q_B .) Following charge separation in the membrane, the $BChl_2$ is re-reduced by the cytochrome at the periplasmic surface, while Q_B , when fully reduced, is protonated at the cytoplasmic surface and released into the pool of free quinone in the bilayer.

Protein

The four polypeptides — L, M, H and a c-type cytochrome — envelop the chromophores. The L and M subunits provide the body of the structure within the membrane. Each forms an open crescent consisting of a curved wall of five transmembrane helices (a–e in the figure). The chromophores are not totally surrounded, so the L–M protein dimer cannot be described as globular. Indeed, since the chromophores are themselves hydrophobic they need not be separated from a lipid environment. Furthermore, BChl must receive energy from BChl in the light-collecting complexes which sit nearby, within the lipid bilayer, and Q_B must exchange with the pool of free quinone in the bilayer. Thus the function may require direct access to the chromophores from the bilayer. For these reasons, the arrangement of hydrophobic protein helices, hydrophobic chromophores and hydrophobic lipid may be rather open.

The transmembrane helices themselves may have three functions. They may surround the chromophores with non-polar side chains designed to hold them in precise relative orientations. In addition, they contribute the single histidines linking the Mg^{2+} of each half of the $BChl_2$ to the protein and the four histidines coordinated to the non-haem iron; two other histidine ligands to BChl and a glutamic acid ligand to the iron are in non-helical

segments of subunits L and M. And they provide an energetically stable conformation for the polypeptide and a smooth exterior facing the bilayer.

Outside the membrane on the periplasmic surface lies the *c*-type cytochrome with its four haem groups arranged in tandem, allowing electrons to jump from one to the other, ready to re-reduce the special pair of BChl. On the cytoplasmic side sits subunit H, of unknown function, but perhaps involved in some way with the function of quinone Q_B and the determination of the mode of interaction with the light-collecting complexes. Both the cytochrome and the H subunit are globular proteins which, although unique in their fold, have structures typical of many water-soluble globular proteins. The H subunit has an amino-terminal hydrophobic tail which forms a single transmembrane helix, much as is presumed to occur in proteins such as glycophorin.

The structure thus provides a detailed and precise three-dimensional model for the events of photochemical energy conversion. It confirms many previous hypotheses based on other methods and allows new propositions to be formulated. For example, since the weak sequence homology between subunits L and M and the proteins D1 and D2 from photosystem II of higher plants is much more convincing when critical residues in the *Rps. viridis* structure are examined, it is now postulated that D1 is homologous to L, and D2 to M, and that D1 and D2 surround the equivalent of BChl₂ in photosystem II of higher plants.

Construction of the X-ray model depended on sequences of the *Rps. viridis* proteins determined by Michel and his colleagues. But the distribution of hydrophobicity in the amino-acid sequences of the same polypeptides in related bacteria had already led to the prediction of a structure containing five transmembrane helices in each of the L and M subunits and one in the H subunit of *Rps. capsulata* and *spheroides*. The qualitative success of these predictions makes one confident that the many other current predictions of the position of helices in membrane-crossing proteins will turn out to be correct, even if they can be made only in broad one-dimensional terms. It now seems likely that α -helices spanning the membrane will form the hydrophobic domains of all membrane proteins and membrane-protein complexes, with the possible exception of those that form very large aqueous channels, where other secondary structures might be preferred.

The open arrangement of the membrane-spanning α -helices in the reaction centre is different from the more tightly packed helices in bacteriorhodopsin (Henderson, R. & Unwin, N. *Nature* 257, 28; 1975), where they have to line a rather more hydrophilic proton channel, and very different from the arrangement in the porins of the outer membrane of *Escher-*

ichia coli, where β -sheets surround an even larger hydrophilic pore (Kleffel, B. *et al. EMBO J.* 4, 1589; 1985).

When more details of the structure become known, it will be especially interesting to see how the redox potentials of the different chromophores and the transfer of electrons between them are regulated by the stereochemistry of their interac-

tions with the surrounding protein. For now, there is much pleasure to be gained simply from contemplating the superb design of a protein that has its body immersed in a lipid bilayer and its head and legs in water. □

Planetary science

Hidden carbon dioxide on Mars

from Robert M. Haberle

THE atmospheres of Venus and Earth are the primary reservoirs for their major constituents: virtually all of Venus's outgassed carbon dioxide is in its atmosphere, and the same is true for nitrogen on Earth. Mars, however, is different. The amount of carbon dioxide in the martian atmosphere, about 7 mbar, is much less than the planet was originally endowed with, and researchers attempting to sort out the climatic history of Mars are keenly interested to know the fate of the rest. In a recent paper, R. Kahn¹ suggests that much of the outgassed carbon dioxide on Mars is tied up in its crust, in the form of carbonate minerals.

It has long been recognized that the carbon dioxide released into the martian atmosphere may have been incorporated into carbonates². If the total amount of carbon dioxide vented into the martian atmosphere were at the high end of the range of estimates (140–3,000 mbar¹), the idea of a carbonate reservoir becomes particularly attractive for several reasons. First, the polar caps and the regolith, the loosely consolidated rocky surface, which are potentially the largest reservoirs for carbon dioxide other than carbonates, do not seem to have the capacity to hold more than the equivalent of about 300 mbar, so that other sinks are required (see the figure). Second, if Mars degassed large amounts of carbon dioxide early in its history, which is consistent with models of the observed nitrogen isotope ratio³, a significant greenhouse warming would have resulted in surface temperatures that could have been high enough to permit liquid water. This is a leading explanation of the 'runoff' channels found throughout the old cratered uplands in the southern hemisphere⁴. In the presence of liquid water, 1 bar of carbon dioxide could be converted into carbonate rocks in the order of 10^7 years⁵.

Kahn's new suggestion¹ is that carbonate formation on Mars continued after open bodies of liquid water became unstable. With an adequate heat source and sufficient quantities of ice, Kahn argues that transitory pockets of liquid water in disequilibrium with their environment could form; in their presence, carbon dioxide would continue to be converted

into carbonates.

A key quantity in Kahn's hypothesis is the minimum atmospheric overburden pressure, P^* , required for liquid water to form. Below that minimum value, ice would sublime before melting. A reasonable lower limit of P^* is 6.1 mbar, the triple point of water, because with atmospheric pressures below the triple point, liquid water would rapidly sublime. An upper limit is much more difficult to determine but may be as high as 30 mbar, though Kahn gives no detailed calculations to support this value. The most interesting consequence of his hypoth-

Possible reservoirs for carbon dioxide on Mars. Of the 140–3000 mbar of carbon dioxide estimated to have been vented into the martian atmosphere, less than 20 mbar can be accounted for in the atmosphere and polar caps, and lost into space. The two most likely reservoirs for the remainder are the regolith, a near-surface layer of pulverized soil created by meteoritic bombardment, and carbonate rocks, a reservoir created by weathering processes.

esis is that, in the absence of a recycling mechanism for carbon dioxide, the surface pressure of Mars will monotonically decline until it reaches P^* , whatever its value. Kahn believes that the surface pressure observed is very close to P^* .

Before the Viking mission, the surface pressure on Mars was believed to be controlled by the temperature of the permanent polar caps⁶. As the caps represent the solid phase of the atmosphere, the annual mean surface pressure must be equal to the saturation vapour pressure corresponding to their average temperature. But Viking found no evidence for substantial permanent polar caps: the carbon-dioxide frost deposits at the north pole completely disappear during northern summer and the amount that remains at the south pole during southern summer is too small to buffer global pressures, and may even disappear completely in some summers⁷. Thus, it seems unlikely that the

polar caps buffer atmospheric pressure.

Kahn's theory has another implication, apart from the explanation of the low surface pressure. If he is correct, the climate of Mars has evolved linearly over geological time, rather than cyclically. This represents a major challenge to current theories of martian climatic history, which generally invoke a periodic exchange of carbon dioxide between reservoirs in the regolith-atmosphere-cap system to explain the polar layered terrains^{2,3}. The exchange, driven by variations in the orbital parameters of Mars, can result in surface pressures that vary from 0.1 mbar at low obliquity (11.7°), to about 15 mbar at high obliquity (37.1°). These variations are thought to modulate the transport and deposition of dust and water into polar regions, so giving rise to the layered terrains. Over many obliquity cycles, the mechanism would substantially deplete the regolith reservoir and eliminate cyclical climatic changes, because conversion of carbon dioxide into carbonates on Mars is irreversible.

Not surprisingly, there are many uncertainties over the plausibility of Kahn's mechanism. Among them are availability of cations, such as Mg²⁺ and Ca²⁺, for carbonate chemistry; the dependence of P^* on heating and soil properties; and whether or not the favoured regions for carbonate formation could be resupplied with water. It would also be worth knowing just how much liquid water is required. Furthermore, no signature of the vast amount of carbonate that must have been produced has been unequivocally identified. Kahn's discussion of these points is mostly qualitative; the basic physics of the process, therefore, remains to be demonstrated. Nevertheless, it is an intriguing idea that merits serious attention. □

Geophysics

Transient mantle rheology

from J. Weertman

CONSIDERATION of the ways in which solids can deform leads to the conclusion that the viscosity of the Earth's mantle should increase with depth. This agrees with our current ideas about the thermal structure of the interior of the Earth. Hence it came as a surprise to find that analyses¹⁻³ of glacial rebound and complementary Earth satellite data indicate that the mantle viscosity does not increase with depth but is almost a constant, with a value of about 10^{21} Pa s. Until now, this has presented a dilemma to those studying the physical structure of the Earth and its consequences for plate tectonics but, in this issue of *Nature*, W.R. Peltier⁴ shows that the problem can be resolved if transient creep is taken into account.

The modern study of the creep deformation of the Earth's mantle started with the suggestion⁵ that the mantle might deform plastically through the diffusional transport of atoms between grain boundaries, the mechanism now known as Nabarro-Herring creep^{6,7}. Using the Nabarro-Herring creep theory, R.B. Gordon⁸ found that the mantle viscosity increases with depth. His result is readily understood. The greater the difference between the actual temperature at a given depth and that at which mantle rock first starts to melt, the larger the expected value of the viscosity. The further rock is from its melting temperature the 'colder' it is (even if its actual temperature is quite high) and the more difficult it is to make the rock creep. As the mantle convects, its thermal profile should be approximately

adiabatic. The adiabatic temperature presumably increases much less rapidly with depth than does the temperature at which melting commences and hence it would not be surprising to find that viscosity increases with depth in the mantle.

This conclusion is not dependent on the choice of the creep mechanism which is used to obtain an estimate of the mantle viscosity. Any such mechanism gives faster creep the closer the temperature is to the melting temperature. It also is not dependent on whether the creep mechanism gives rise to a linear, newtonian creep equation ($\dot{\epsilon} = \sigma/\nu$) or to a non-newtonian creep equation such as a power-law creep equation ($\dot{\epsilon} = c\sigma^n$). Here $\dot{\epsilon}$ is the creep rate, σ is the stress, ν is the viscosity and c and n are constants. (For non-newtonian creep an effective viscosity is defined to be equal to $\nu = \sigma/\dot{\epsilon}$. The effective viscosity for non-linear creep requires that a standard stress level or strain rate be specified.)

That the mantle viscosity is almost constant could be explained, of course, if the ratio of the actual temperature over the melting temperature were constant throughout the mantle. It is more likely, however, that this ratio decreases with depth. It could also be explained if mantle creep obeys a power law⁹ and the creep stress increases with depth at a suitable rate. But the glacial rebound stresses decrease with depth. One possible way out of the dilemma is to bring transient creep phenomena into the analysis. In analyses carried out up to now it has been assumed implicitly that only steady-state creep

equations need be considered.

Analyses of isostatic geoid anomalies^{9,10} indicate that the lower mantle has viscosity an order of magnitude greater than that of the upper mantle and hence than the lower mantle viscosity as determined from glacial rebound. But geoid isostasy operates on a timescale of the order of 10^6 years rather than the 10^4 – 10^5 years for glacial rebound. Peltier⁴ investigates whether the order of magnitude difference of viscosity of the lower mantle as deduced from the two phenomena could arise if the glacial rebound method measures a predominantly transient creep strain rate and if the isostatic geoid anomaly method measures a more steady-state creep strain rate.

Peltier makes an explicit calculation by use of a linear creep equation that reduces to a steady-state equation at long times but is a transient equation at shorter times. This equation is for a Burgers's solid¹¹ which, when springs and dashpots model the solid, is simply a Zener standard linear solid in series with a dashpot. For uniaxial stress-strain the equation he used can be written as $\dot{\epsilon} + (\sigma/\tau) + (\mu^*\sigma/\nu\tau) = \mu\dot{\epsilon} + \mu^*(\dot{\epsilon}/\tau)$ where the dot stands for time differential, τ is a decay time, μ and μ^* are elastic moduli and ν is the long-term viscosity. Peltier uses this equation only for the lower mantle. For the upper mantle he uses a Maxwell solid (spring and dashpot in series) with the equation $\dot{\epsilon} = (\dot{\sigma}/\mu) + (\sigma/\nu)$. He is able to show that it is possible to reconcile the two values of the viscosity of the lower mantle. He points out that further constraints on the transient creep contribution to lower mantle deformation may require reexamination of the analysis of Richards and Hager¹⁰.

Since Peltier's paper was submitted for publication, a paper by Sabadini, Yeun and Gasperini¹² has appeared in which a transient creep analysis also based on a Burger's solid has been carried out. The results and conclusions are very similar to those of Peltier. Clearly, the study of the rheology of the mantle is entering a new period in which many possible creep mechanisms are being considered as rate controlling, and in which the theorists have become capable of carrying out quite sophisticated studies involving transient creep of mantle rocks. □

Plant tumours

Wounds activate attackers

from John E. Beringer and Colin M. Lazarus

THE ability of strains of *Agrobacterium* to induce tumours on dicotyledonous plants has excited the interest of most biologists, particularly since it was discovered that tumour formation results from the inheritance of DNA (T-DNA) transferred from the bacterium to the plant, a process that depends on the function of virulence (*vir*) genes. Tumours are induced only where there is a wound on the plant and an intriguing question has been how *vir* genes are regulated so that *Agrobacterium* can recognize wounds and initiate T-DNA transfer. The answer, provided by S.E. Stachel *et al.* on page 624 of this issue, is surprisingly simple: the *vir* genes are induced by specific signal molecules, acetosyringone and α -hydroxy-acetosyringone, that are produced by wounded, but not by intact, plant cells.

This finding helps us to understand why wounds are required and demonstrates yet again how much tumour formation depends on interactions between the two partners. A series of interactions can now be recognized that are logical and all, apparently, directed towards optimizing the efficiency of the interaction from the point of view of the bacterium.

T-DNA is present as part of a large extrachromosomal molecule (plasmid) that also carries a number of *vir* genes. Like other DNA elements capable of transposition, T-DNA is bounded by identical repeats of DNA. Independent loops of T-DNA are found when *Agrobacterium* is cultured in the presence of plant cells and it is assumed that these are T-DNA intermediates in the transfer to the plant cells. Seven genes are required for T-DNA transfer. Two of them, *virA* and *G*, are expressed in vegetative cells but the other five are induced only in the presence of acetosyringone or α -hydroxy-acetosyringone.

Once it is transferred to the plant, T-DNA integrates into host DNA and the genes it carries are expressed. T-DNA encodes genes involved in the synthesis of plant hormones and for the synthesis of novel compounds (opines) that are produced only by plant cells containing T-DNA from *Agrobacterium*. Tumour formation appears to be a method evolved by *Agrobacterium* for inducing the plant to produce a large number of cells that synthesize opines, which are metabolized by *Agrobacterium* but by few other organisms.

Opines have also been shown to act as specific inducers of the transfer (*tra*) genes carried on *Agrobacterium* tumour-inducing (Ti) plasmids. It is now clear that plant metabolites induce the functioning of two distinct sets of *Agrobacterium*

genes: those for virulence and those for transfer of Ti plasmids. In both cases, DNA replication and mobilization leading to gene transfer are induced only when they are likely to be of direct value to *Agrobacterium*.

As well as answering the immediate questions of why only wounded tissue is infected by T-DNA, Stachel *et al.* may also have resolved the enigma of why strains of *Agrobacterium* carrying *Rhizobium* nodulation genes form nodules on the roots of appropriate legumes, whereas they induce tumours when inoculated on wounded tissue; presumably the close association of the bacteria and plant cells during nodule development does not lead to the induction of *vir* genes because the plant is not wounded.

This report is another example of how the study of plant-microbe interactions can yield important information on genetic regulation. Building on evidence that plant defences against pathogenic fungal attack are triggered by fragments of the host plant cell wall, K. Tran Thanh Van *et al.* (*Nature* 314, 615; 1985) have recently

shown that specific oligosaccharides can affect the developmental fate of plant cells in culture. This indicates a role for such 'oligosaccharins' in normal organogenesis. Recently J.T. Mulligan and S.R. Long (*Proc. natn. Acad. Sci. U.S.A.* 82, 6609; 1985) and L. Rossen, C.A. Schearman, A.W.B. Johnston, and J.A. Downie (*EMBO J.*, in the press) have reported that a *Rhizobium* nodulation gene is induced by root exudates in an analogous manner to *Agrobacterium vir* genes. These findings identify primary signalling molecules and raise questions concerning the transduction of signals from the cell surface to the genetic material.

What about interactions such as those of mycorrhizas and between host plants and other pathogens? Progress

in the search for similar inducers may be slow. As Stachel *et al.* have shown, finding an effect of root exudates is only the beginning of a complex isolation and characterization process. To purify the molecules responsible it is necessary to have a good assay, which in general is not an assay of a plant response. Both Mulligan and Long, and Stachel *et al.* took advantage of the extensive genetic understanding of *nod* and *vir* genes, respectively, to produce fusions of these genes with the *Escherichia coli lacZ* gene and thus could determine induction by measuring β -galactosidase activity using a simple and sensitive assay procedure.

We look forward to seeing a surge of activity in the identification of plant molecules that act as specific inducers of genes in symbiotic and pathogenic microorganisms. Perhaps, as with other aspects of plant-microbe interactions, work will be driven by studies of the genetically well-characterized bacteria *Agrobacterium* and *Rhizobium*. It is good to see that studying the biology of tumour formation can yield results that are at least as satisfying as those obtained through molecular studies of DNA.

The spider, *Subantarctia* sp., forms the frontispiece to the first formal presentation of the *Orsolobus* taxon of spiders, members of which are found in South America, Australia and New Zealand (Forster, R.R. & Platnick, N.I. *Bull. Am. Mus. nat. Hist.* 181, 1; 1985). The fly is the frontispiece to a taxonomic study of the ichneumon-fly genus *Banchus* in the Old World (Fitton, M.G. *Bull. Br. Mus. nat. Hist.* 51, 1; 1985).

Biophysics

XANES spectroscopy and the crystallographic imperative

from John Galloway

PERHAPS nowhere in the determination of molecular structure is precision more at a premium than in the case of metalloproteins, so that any method that promises to enhance or improve on single crystal protein crystallography is worth investigating. X-ray near-edge structure (XANES) spectroscopy is claimed to represent such promise. The real question, of course, is whether that promise can be realized; in the paper by A. Bianconi *et al.* on page 685 of this issue we might have had the first chance, to find out. As it happens, we don't.

What exactly is XANES? Absorption of X-rays takes place chiefly through the photoelectric effect. An electron is ejected from the K shell of an atom (or possibly some other shell). Its chances of escaping are modulated by its being scattered by neighbouring atoms. The resulting fine structure in the absorption cross-section expressed as a function of the energy of the incident X-ray photon contains information about the local atomic geometry. For energies not much in excess of the threshold represented by the absorption edge, say within 50 eV, the photoelectrons are strongly and multiply scattered. These modulations are referred to as XANES.

At higher energies the scattering is weaker and dominated by single scattering events. In this energy regime the fine structure is the rather better known extended X-ray absorption fine structure (EXAFS), which has been widely used in various types of structural study, including some on metalloproteins, since about 1972, the year in which it first became possible to replace the conventional X-ray tube by synchrotron radiation. The domination by single scattering events confers on EXAFS an immediate advantage it shares with a number of other physical probes of structure, namely that it is relatively easily interpreted. But it also confers the considerable disadvantage that it contains information only about two-particle correlation functions, so that only the *radii* of the coordinating shell of atoms and slightly more remote shells in metalloproteins can be extracted.

XANES, by virtue of its strong multiple scattering, contains information about three- and higher-order correlations. Thus, in principle, information about the detailed geometry of arrangements in the shells should be extractable — angles as well as distances. A lot is made of this feature by Bianconi *et al.* The Fe–C–O bond angle is obtained in a single crystal of carboxymyoglobin from the angular de-

pendence of the XANES spectrum, and a difference in this angle between carboxymyoglobin and carboxyhaemoglobin is shown to exist in solution. Unfortunately, the paper gives no indication of the accuracy of these measurements although it is unlikely to be better than $\pm 10^\circ$. On the face of it this seems to compare quite well with the angular accuracy that can be achieved by conventional crystallography but the question is not explicitly addressed by the authors.

That XANES might be interesting at all to structural biologists is a consequence of the two cardinal deficiencies of single crystal methods. First, that they are obviously only suited to crystals, whereas XANES and EXAFS can and do provide structural information about proteins in solution. Second, that in single crystal determinations the extent and quality of the data limit accuracy; limited resolution and phasing errors typically lead to a precision in atomic position of no better than 0.3–0.5 Å, although with great care standard deviations on atomic positions can be brought well below 0.1 Å, which will be needed for understanding function in metalloproteins, where distances between metal ions and their ligands may need to be known to better than 0.1 Å resolution.

Without a good idea of a method's accuracy, realized or potential, no technique will or should be taken seriously. Early proponents of EXAFS rashly made unfounded claims of its superiority over crystallographic analysis of haemoglobin (Eisenberger, J.B. *et al.* *Nature* **274**, 30; 1978) and got a bloody nose for their pains (Perutz, M. *et al.* *Nature* **295**, 535; 1982). But EXAFS has been rehabilitated

through very careful comparisons with crystallographic analysis on 2Zn insulin (Bordas, J. *et al.* *Proc. R. Soc. B* **219**, 21; 1983) and on haemoglobin and insulin (Dodson, G. *Proc. Bioinorganic Discussion Group*, Daresbury, in the press). Dodson concludes that EXAFS has a "clear role in adding precision to the crystallographic picture and hence furthering our insight into the chemical and structural processes that are at the centre of biological phenomena".

Whether the same is true of XANES will be found only in much the same way and will not be easy. It is crucial that the early mistakes made with EXAFS are not repeated with XANES, necessitating rescue operations at a later date. Systematic comparative structural studies of XANES and conventional crystallographic analysis now will pay dividends. The advantage of crystallographic analysis is that production of the electron-density map is not subject to the experimenter's anticipation. XANES is model-dependent — a structure must be imagined and its consequences compared with the experimental data. So the only sound tactic is a heavy investment of effort in alternative structures — a prominent feature of the papers of both Bordas *et al.* and Dodson.

XANES analysis tends to be very heavy on the time of both experimenters and computers. Furthermore, it has inherent limitations, as pointed out by J. B. Pendry (*Comments Solid State Phys.* **10**, 219; 1983). The range of data is small and will not generally be expected to contain many features to be fitted to the model. Indeed, it seems highly optimistic to suppose that the positions of more than three atoms will be found with any accuracy. Therefore, it will not be useful except in harness with other methods and even then its usefulness is likely to lie in choosing between qualitatively different structural alternatives where much is already known. □

Ecology

Rats as agents of extermination

from Jared Diamond

"TAKE care! Kingdoms are destroyed by bandits, houses by rats, and widows by suitors!" Biologists would emend this insight of the 17th century Japanese poet Ihara Saikaku to note that rats destroy not only houses but also island biotas. The colonization of islands by rats has outweighed all other causes of extinctions of island birds. Rats have also preyed on young Galapagos giant tortoises and exterminated small mammals, large insects, molluscs (Hawaiian achatinellid land snails), and cold-blooded vertebrates (most ground snakes and lizards of Mauri-

tius plus mainland frogs, lizards and tuataras of New Zealand).

Yet it has proved hard to make sense of these gruesome facts. Rats have caused catastrophic extinction waves on some islands, a few extinctions on others, and no visible effect on still others. Somehow, these varying outcomes must depend on the differing susceptibilities of prey species, and on the differing biologies and histories of the three species of rats involved. Ian Atkinson of the New Zealand Department of Scientific and Industrial Research has now made a major contribu-

tion to sorting out this confused situation (in *Conservation of Island Birds* ed. Moors, P.J., 35; International Council for Bird Preservation, Cambridge, 1985). By scrutinizing historical records for the past several thousand years, Atkinson has been able to reconstruct the spread of each rat species. He has thereby established both how the impact of each species differs and the variation in the susceptibility of different faunas exposed to the same rat species. Atkinson's conclusions are not only important to conservation biologists but have also yielded an unexpected insight into the evolution of predator avoidance behaviour.

The three main commensal rat species are the Polynesian rat *Rattus exulans* (here abbreviated *RE*) originally native to tropical southeast Asia, the ship or black rat *R. rattus* (*RR*), from India and southeast Asia, and the Norway or brown rat *R. norvegicus* (*RN*), originally from Siberia and China. These rats reach islands as stow-aways on ships. The first expansion (1500 BC–AD 1000) was of *RE*, which reached Pacific islands on Polynesian canoes. From AD 1500–1700 *RR*, by then established in Europe, was spread by ship to islands of the Atlantic and Indian Oceans. By 1716, *RN* had largely displaced *RR* in Europe and was the main rat to ride ships to islands, including some in the Pacific. After 1850, for unknown reasons, *RR* again became the dominant shipboard rat. The spread of rats to islands has proceeded at a fairly steady rate from 1850 to the present, with a peak during and after the Second World War related to establishment of military bases on islands.

With this knowledge of what islands acquired which rats and when, Atkinson then identified the impact of each species. *RE* can climb trees but is the smallest of the three rats and, in terms of documented victims, seems to prey on the fewest species of birds. It may, however, have claimed many undocumented and long extinct species on the Pacific islands during its expansion before AD 1000, and it does still limit the distribution of some invertebrates and cold-blooded vertebrates. (Ironically, the largest bird known to be killed by any rat, the Laysan albatross *Diomedea immutabilis*, is a victim of the smallest rats *RE* — see figure). The largest species, *RN*, climbs trees infrequently and has mainly devastated ground-nesting or burrow-nesting birds, especially seabirds. *RR* is medium-sized but an agile climber and preys on birds at any height from the ground to the canopy. Rats can also have an indirect effect on island biotas by acting as prey for predatory cats, weasels and mongooses, which might otherwise not survive and which also prey on island native species.

In three or four notorious cases, invasions of formerly rat-free islands by rats have rapidly been followed by biological catastrophes. For example, three years after *RR* reached Big South Cape Island (off

Pacific rat approaching (inset) and eating a Laysan albatross. (Photo courtesy Cameron Kepler.)

New Zealand) in 1962, it had reduced or exterminated over 40 per cent of the island's landbird species plus the last surviving population of the southern short-tailed bat. *RR* caused similar catastrophes on Lord Howe Island in 1918, Midway in 1943, and probably Hawaii in the late 1800s. On the other hand, numerous islands with endemic native rats have survived the arrival of *RR* (and sometimes also *RN*) without any subsequent extinctions of birds. This was the case, for example, in the islands of Galapagos, Christmas (Indian Ocean), West Indies, Andaman, Nicobar, New Guinea and the Solomons.

This contrast suggests that birds that have co-evolved with native rats develop predator defence behaviours that allow them to survive invading rats. This, however, is not the sole or even main reason why islands biotas differ in their susceptibility to rats. Many initially rat-free tropical islands (Fiji, Samoa, Tonga, Marquesas, Aldabra and others) have survived colonization by rats without catastrophe. Atkinson notes that land crabs, which are widely distributed on tropical islands, are not only scavengers and grazers, as usually assumed, but also eat birds' eggs and chicks; moreover, some species (especially the giant coconut crab *Birgus latro* and some hermit crabs) climb trees. Thus, they are the invertebrate equivalents of rats, and co-evolution of birds with land crabs may lead to the development of anti-predator behaviour that also protects the birds against invading rats.

Atkinson's analysis has identified new questions. Why did *RR* partly displace the larger *RN* on ships after 1850? Will archaeologists in Polynesia document waves of extinction attributable to the arrival of *RE* with the first Polynesians? What was the original distribution of land crabs? What, specifically, are the predator defense behaviours that are produced by co-evolution with rats, and perhaps land

crabs?

But the most important problem is a practical one. Gough, Inaccessible, Nightingale, Clipperton, Snares, Laysan, and some Galapagos islands, to name just a few, remain rat-free. Other islands, including Rennell, Bellona, Rose, Henderson and Little Barrier, have received *RE* but not the deadlier *RN* and *RR*. These islands contain endemic species or relicts that need preserving as biological treasures. The arrival of rats on these islands could produce biological catastrophes but, contrary to common pessimistic assumptions, it is not inevitable that rats will arrive. Atkinson lists specific measures that reduce the risk. An immediate task is to secure the future of the remaining islands. □

THE CONTINUITY OF THE GERM-PLASMA CONSIDERED AS THE BASIS OF A THEORY OF HEREDITY

THE present essay deals not with the entire subject of heredity, but with the fundamental question. How is it that a single cell of the body unites within itself the entire tendencies of inheritance of the whole organism? There are only two physiologically conceivable possibilities by which germ-cells endowed with such peculiar powers as we know them to possess can be produced. Either the substance of the parent germ-cell after passing through a cycle of changes required for the construction of a new individual possesses the capability of producing anew identical germ cells, or the germ-cells arise as far as their essential and characteristic substance is concerned, not at all out of the body of the individual, but direct from the parent germ-cell.

It is this latter view which Prof. Weismann holds to be correct, and maintains in the present essay, and which he terms the theory of the continuity of the Germ-plasma.

Astrophysics

Bipolar wind from young stars

from James P. Emerson

THE molecular cloud L1551 contains the best example of a collimated bipolar high-velocity molecular outflow driven by a young stellar object. Now high-resolution ^{12}CO observations have directly demonstrated the postulated windswept cavity and shell in this cloud (Snell, R.L. & Schloerb, F.P. *Astrophys. J.* **295**, 490; 1985). The complex observed morphology and kinematics can be neatly explained by the combination of two effects. First, a collimated high-velocity flow from the young stellar object IRS5 (infrared source 5) sweeps out a bipolar cavity in the molecular cloud, and compresses much of the material into a dense thin shell surrounding the cavity; and second, the cavity expands uniformly into the surrounding cloud. The biggest puzzle of all, however, still remains — what causes the collimated bipolar wind from the young star in the first place?

A key problem of astrophysics is the formation and early evolutionary stages of stars. Interpretation of the observations of young high-mass stars is particularly complicated because they are usually associated with clusters of other nearby stars, surrounding ionized hydrogen regions, ionization fronts and shocks. Therefore, many researchers hoped to get a clearer picture of star formation from studying low-mass stars forming in dark clouds, because these are relatively isolated objects and not expected to be associated with the

complexities of ionized hydrogen regions.

Far from the anticipated simplicity, there has instead been mounting evidence that energetic jets and collimated outflows are commonly associated with young stars, even those of low mass. The energy input into the surrounding clouds from these bipolar winds could significantly affect the subsequent evolution of the cloud and its star-forming history. Some of these problems are analogous to those involved in understanding jets from galaxies, although jets from young stars are non-relativistic and do not involve such great energies (see Lada, C.J. *Ann. Rev. Astron. Astrophys.* **23**, 267; 1985).

When molecular-line observers first turned their telescopes towards the candidate young star IRS5, which is in the dark cloud L1551, they were surprised to find, in addition to the expected low-velocity molecular gas associated with the dark cloud, blueshifted and redshifted high-velocity gas located in oppositely directed bipolar lobes on the sky (see figure). The south-west lobe contains blueshifted gas and the north-east lobe redshifted gas. In the approaching lobe optical nebulosity can be seen because the flow is coming out of the dark cloud, but in the receding lobe no nebulosity can be seen because of the obscuring dust.

Although many examples of bipolar molecular outflows have now been found, L1551 remains prototypical as its proximity

and orientation make it especially favourable for detailed observational study. Optical studies of the south-west lobe have identified shock-excited knots of gas (termed Herbig-Haro objects) whose proper motions are radially outwards from IRS5. Optical and high-resolution radio observations have both shown ionized jets emanating from IRS5 parallel with the much larger-scale bipolar outflow and orthogonal to a dense rotating torus of high-density material seen in CS (carbon monosulphide) observations and suggested by infrared polarization studies. Shock-excited molecular hydrogen is

found at the edge of the flow, and some of the optical nebulosity is interpreted as reflected light from IRS5.

Snell and Schloerb have produced a complete ^{12}CO map of L1551 in the 2.6-mm line with the highest angular resolution ($45''$) yet used on this flow, together with lunar occultation measurements of $7''$ resolution which clearly show the cavity and shell, and demonstrate that each lobe can be considered to be divided into two velocity components. The lower velocity component is in a thin shell at the periphery of the higher velocity component and contains a substantial fraction of the 0.9 solar masses of material in the outflow. The data and the overall flow shape can be neatly and consistently interpreted in terms of the collimated bipolar wind from IRS5 driving gas radially outwards at about 12 km s^{-1} , while the bubble thus created expands uniformly at a velocity of about 4 km s^{-1} . The mass now contained in the cavity and its surrounding compressed shell is close to that expected to be swept up if the cavity volume originally contained molecular gas at the ambient density of the undisturbed central parts of the cloud.

As Snell and Schloerb point out, although the mechanical luminosity of the wind is only a small fraction of the luminosity of the embedded star, the mechanism by which the energy of IRS5 is converted into momentum in the flow is as unknown in L1551 as it is in the other examples of this phenomenon.

It is widely believed that many young stellar objects, still evolving towards the main sequence, are surrounded by remnants of their parent cloud in the form of a rotating circumstellar torus or disk. It is crucial for theories of the formation of planetary systems and stars that the disks and their interaction with the stars and their immediate environment be understood. These disks are commonly assumed to be involved in the production of jets and bipolar outflows by an interaction between the young star and the surrounding torus or disk of material. It is thought that the interaction producing the jets is mediated by some combination of local density structure, magnetic fields, rotation and accretion of material, but theoretical models have failed to provide any widely accepted explanation.

Many of the current observations make use of techniques such as interferometry and polarimetry in the infrared and millimetre spectral regions in attempts to identify clearly these disks and to define their properties and how they relate to the jets (for example, Beckwith, S. *et al. Astrophys. J.* **287**, 793; 1984 for HL Tau, which also lies in L1551), but it seems more probable that a new theoretical model is required to explain how the collimated jets from young stars are driven. □

James P. Emerson is a Lecturer in Physics at Queen Mary College, Mile End Road, London E1 4NS, UK.

An earlier lower resolution ^{12}CO contour map of the L1551 outflow (from Snell *et al. Astrophys. J.* **239**, L17; 1980) in the broad-velocity components, superimposed on an optical photograph of the L1551 region. Dashed contours, redshifted molecular gas; solid contours, blueshifted gas. Also shown are the direction of the proper motions of the two compact Herbig-Haro objects, HH28 and HH29; tracing their motion backwards suggests a common origin at IRS5 (cross). α , Right ascension; δ , declination.

Drosophila development

Homing in on homoeo boxes

from Geoffrey North

SINCE its discovery^{1,2} as a short repeated sequence within the homoeotic gene complexes of the fruitfly *Drosophila melanogaster*, research on the 'homoeo box' has taken three more or less independent directions. One has been the pursuit of evidence that the presence of homoeo boxes in the genomes of other species really does signify that they have equivalents of the fruitfly's homoeotic genes. The state of this particular art was discussed recently in these columns³. A second has been cataloguing of all *Drosophila* genes that have homoeo boxes, the newest member of the club being *caudal*⁴, which is the first example that is 'maternally expressed' and so presumably concerned with the very earliest events of development. And the third has been the attempt to ascribe a function to the homoeo box. This has now borne fruit, with the evidence reported by C. Desplan, J. Theis and P.H. O'Farrell on page 630 of this issue⁵ that the protein domain encoded by the homoeo box of the *engrailed* gene of *Drosophila* has sequence-specific DNA-binding activity.

But first some recent history. Shortly after their discovery^{1,2} as repetitive sequences of both the bithorax and Antennapedia gene complexes of *Drosophila*, homoeo boxes were found to encode roughly 60 highly-conserved amino acids, which would form a domain within the protein products of each of the genes that constitute these complexes. Although most of these genes are strictly homoeotic in that their mutations cause clean transformations of one body-part into another, one of the first homoeo boxes to be sequenced belongs to a rather different kind of gene. This is *fushi tarazu*, the odd-man out in the Antennapedia complex, which falls into the 'pair-rule' class of segmentation genes: in *fushi tarazu* mutant embryos, equivalent regions of every other segment are deleted.

The diversity of genes that contain a homoeo box was increased still further with *engrailed*^{6,7} — the first to be found outside the bithorax and Antennapedia complexes. *Engrailed* has some properties in common with the classical homoeotic genes, but others that are more reminiscent of segmentation genes such as *fushi tarazu*. Thus it seems to specify the posterior compartment of every segment of the developing fruitfly, for if clones of mutant cells lacking wild-type *engrailed* activity are created in a posterior compartment they develop as though they were in the equivalent region of the anterior compartment of the same segment. But in *engrailed* mutant embryos, unlike classical homoeotic mutants, the pattern of seg-

mentation is disrupted. In fact, the effect resembles that of a pair-rule mutation, which may relate to the observation that the developing pattern of *engrailed* expression, which in its final form is a series of stripes corresponding to the eventual pattern or morphological segmentation, goes through an intermediate stage with a clear-cut two-segment periodicity^{8,9} (see figure).

Thus, although all of the *Drosophila* homoeo-box-containing genes, including *caudal*, seem to have interesting roles in

Expression of *engrailed* with a two-segment periodicity (from ref. 8).

development, at the macroscopic level they seem to have a variety of types of function. But the implication of their shared homoeo-box domain is that at the molecular level the products of these genes work in basically similar ways. A clue as to what this common activity might be has come from the homology of the *Drosophila* homoeo boxes to regions of the yeast *MAT a* and *MAT a2* genes^{10,11}, which are known to regulate sets of genes that determine the mating type of haploid yeast cells. The protein product of the *MAT a2* gene has recently been shown to bind specifically to a sequence located upstream of the genes that it regulates¹².

It is against this background that Desplan *et al.* have tried to determine whether, as widely predicted, the *Drosophila* homoeo boxes also encode DNA-binding domains. Following a similar approach to that of Johnson and Herskowitz in their study of the yeast $\alpha 2$ protein, Desplan *et al.* have constructed fusion proteins in which different regions of the *engrailed* protein product are tagged on to the end of the enzyme β -galactosidase. Expressed from hybrid genes introduced into the bacterium *Escherichia coli*, high enough levels of these fusion proteins can be obtained for biochemical studies.

Compared with Johnson and Herskowitz, however, Desplan *et al.* were at a disadvantage, for they had no prior indication of the sequences to which the *engrailed* protein might bind. So at first they simply tested whether their fusion proteins would bind non-specifically to frag-

ments of the bacteriophage lambda genome. Indeed, they found that those fusion proteins that contained the *engrailed* homoeo-box domain did have DNA-binding activity. But was this simply due to a non-specific interaction between acidic DNA fragments and the basic protein molecules? It seems not, for under more stringent conditions it was revealed that some of the lambda fragments are bound much more avidly than others. This is a clear sign that the DNA-binding activity of the fusion proteins is of the legitimate, sequence-specific kind. Presumably it is just by chance that some lambda fragments fulfill some of the sequence requirements for binding the *engrailed* protein, but it could well be that the fusion proteins are rather less choosy *in vitro* than *in vivo* (where their specificity might well be increased by interactions with other proteins).

Finding the functionally significant sequences of the *Drosophila* genomes to which the *engrailed* protein is presumed to bind is a more difficult problem, which Desplan *et al.* have approached by following the increasing genetic evidence that genes such as *engrailed* are involved in mutual regulatory interactions. They have therefore looked for and found binding sites for the *engrailed* protein upstream of the *engrailed* gene itself — but, as the authors themselves stress, this highly intriguing result must be interpreted with caution, for the affinity of the protein for these sites is not significantly different from that for its favourite fragments of the lambda genome. The binding sites near the *engrailed* gene are conserved between two different *Drosophila* species, however, which implies some functional significance. If it turns out that they are not true binding sites for the *engrailed* protein perhaps they are binding sites for some other protein that contains the homoeo-box domain. An example would be the product of the *fushi tarazu* gene, which recent genetic evidence suggests is involved in establishing the pattern of *engrailed* expression during the early development of *Drosophila* embryos (Phil Ingham and Ken Howard, personal communication).

Quasiperiodic order in dissipative systems

SIR—The concept of quasicrystalline order¹ in relation to experimental observations²⁻⁴ in Al_3Mn suggests that quasiperiodic structures are also likely to appear in driven systems undergoing patterning instabilities. (Classical examples are given by convective instabilities in fluids⁵ or Turing instabilities in chemical systems, for example, ref. 5). Despite the complexity of the dynamics, such symmetry-breaking instabilities may be described near threshold by a kinetic equation for the unstable or critical modes which play the role of an order parameter. They are related for example to the velocity field in hydrodynamical systems or to the concentration of active species in chemical systems^{6,7}. The stabilities of the patterns may be ordered in decreasing values of the associated Lyapunov functional which plays the role of the Ginzburg-Landau-Brazovskii potential in equilibrium situations.

Near threshold, structures built on wavevectors of critical wavelength may be stable and when the Lyapunov functional is limited to its fourth order invariant a situation very similar to the Landau treatment of crystallization is recovered⁸. Among the possible patterns one finds, for example, layered structures corresponding to modulations in one direction only, bimodal patterns and structures with triangular or cubic symmetry corresponding to combinations of critical modes with wavevectors forming equilateral triangles⁷.

However, we have to keep in mind that the kinetic equation for the order parameter-like variables is obtained via the adiabatic elimination of stable noncritical modes which are driven by the critical ones. Hence their contribution may become important for increasing values of the bifurcation parameter. As a result, the intensity of the coupling between three modes is renormalized and, furthermore, higher order nonlinearities are generated by the driven modes as in the multicomponent Landau theory⁴. The first nonlinear coupling induced by this effect in the kinetic equation involves four critical modes corresponding to a fifth order invariant in the Lyapunov functional³. This term favours the formation of structures built on wavevectors forming an equilateral pentagon which in two-dimensional systems has the symmetry of a Penrose lattice.

The emergence of high order nonlinearities in the dynamics of the critical modes favouring quasiperiodic patterns is a general feature of this description of systems undergoing symmetry-breaking instabilities^{6,7}. Hence, according to the intensities of the nonlinear couplings which are system dependent, quasiperiodic structures could become the stablest ones

in some range of the parameters. Having a dominant growth rate versus layered structures they should also appear after sudden increases of the control parameter.

In various convective instabilities, the increase of the constraint beyond threshold leads to the nucleation of defects and ultimately to the destruction of the translational order⁹. It was suggested that this effect could be related to a dislocation induced melting similar to what happens in two-dimensional solids^{9,10}. From the present analysis, however, one may also expect the appearance of quasiperiodic structures well beyond threshold. It would thus be interesting to perform diffraction experiments for such systems after slow and sudden increases of the bifurcation parameter in the region where translational order is lacking to test whether the disorganization is related to a dislocation-induced melting or to the transition from periodic to quasiperiodic structures.

The cosmic connection of catastrophism?

SIR—The remarks by Weissman¹ on the review by Maddox² require some additional comment. This relates to a possible extraterrestrial cause of terrestrial catastrophism and, in particular, to the origin of the suggestion that this might be associated with the Sun's motion in the Galaxy.

As previously pointed out in these pages³ pulsations are not a new idea and were suggested more than half-a-century ago⁴. Later, in 1947, Umbgrove⁵ reasoned that the Earth had a periodicity of about 250 Myr and drew attention to the similarity between this and the galactic day. Although Umbgrove was probably the first to make such a suggestion, the validity of much of his evidence can certainly now be questioned⁶.

Probably the first experimental measurements relevant to this topic were carried out in the early 1960s⁷ and the re-

sults were published in this journal in 1971⁸. These measurements indicated that the times of emplacement (in Myr) of mantle-derived carbonatites (for at least the last 1.7 Gyr) could be approximated very closely by the relationship $T_n = 233n - 102$, with n integral. The similarity of this period with that for galactic rotation was then noted. The significance of the data set used in deriving this conclusion has since been tested⁹. From other evidence Innanen *et al.*¹⁰ have subsequently proposed a galactic model from which they derive an identical numerical value of 233 Myr for the length of the galactic year.

In 1971, plate tectonics was in its infancy and episodicity and global synchronicity were rather unfashionable concepts in geology. Over the years, this data set has therefore been continually expanded and improved¹¹ and incorporated into a hypothesis of Earth behaviour¹², compatible with plate tectonics, which nonetheless preserves this fundamental periodicity. This hypothesis is testable by carrying out more accurate age measurements on carbonatites.

One striking feature of the time distribution is the near coincidence of times T_1 , T_2 and T_3 with the boundaries of geological periods in Phanerozoic time¹³. It is therefore tempting to extrapolate backwards ($n \geq 4$) for a Precambrian time-scale. Another corollary of this hypothesis is that, as a large number of carbonatites exist with ages around 65 Myr (see, for example, refs 12, 14), an atmospheric spike of carbonatite-derived CO_2 may have influenced events near the Cretaceous-Tertiary¹⁵ boundary. This temporal coincidence can again be tested by accurate geochronological measurements. Whether, in addition, widespread carbonatite emplacement can explain the well-documented geochemical anomalies associated with this boundary is currently being examined by analysing rocks from (dated) carbonatite complexes which were emplaced across the boundary.

Radiant Science, Dark Politics: A Memoir of the Nuclear Age. By Martin D. Kamen.

University of California Press: 1985. Pp.348. \$19.95, £16.95.

ON August 6, 1945, I was at a camp at Titchfield, Hampshire, England, when I heard the news that an atomic bomb had been dropped on Japan. A year later I began my studies in physics for the DPhil. at Oxford. There, in the Clarendon Laboratory, I met some of those who participated in the atomic bomb programme, among them "Jim" Tuck, who had gone to Los Alamos as an explosives expert and returned to build a betatron, and Professor Franz E. Simon, who with others had worked on gaseous diffusion in the rooms below the undergraduate optics laboratory.

In that winter of 1946–1947, the severe weather prevented transport of coal from the mines to power stations for nearly six weeks; stocks were low and Britain had its first electricity rationing. As physicists we realized that this short-term problem was merely an indicator of a future long-term one, and at tea times discussed the solutions to the "energy crisis". On the one hand, we could burn coal more efficiently, and with less environmental disadvantages; gasify it underground and use the gas in a thermodynamically efficient fuel cell. And then there was nuclear power.

Since 1939 it had been clear that nuclear fission might be used either for power or for bombs. The Second World War had given work on bombs priority, but after 1945 scientists returned to their first love, nuclear electric power. The problems of proliferation of weapons among countries were clear. We concluded that within 30 years (by 1976) 30 countries could and would have bombs. But we were pessimistic: most countries that could do so have declined to make them. In another way, we were too optimistic. It never occurred to us that two countries, the United States and the Soviet Union, would possess tens of thousands each.

We were over-optimistic, too, about the speed of nuclear power development; instead of the five years expected, it took ten years to produce the first power plant (in Britain in 1956) and 25 additional years for much market penetration. We were at the same time pessimistic about the need for power. We had not anticipated that oil from the Arabian (at that time Persian) Gulf would be available at such an incredibly low cost.

We were very aware of the environmental advantages of nuclear power. Many of us had lived in London in the days of the bad fogs, and it must be remembered that the fog of early December 1952, which caused 4,000 "excess deaths", was far from the worst; it was merely the first about which there are good health statistics. At the same time we were all well aware that nuclear power is only conditionally safe — conditional on the technology being designed and operated well.

What went wrong with our projections? Why, after a promising start 30 years ago, is the nuclear power industry in such trouble in the United States? Why is the number of bombs increasing, apparently without limit? In other words, how did we get to here from there?

With all the many books about nuclear electric power that have been written, I have found none that discusses this all-important question. To illustrate this surprising omission of the world's scribblers, I discuss three of the recent books about the nucleus and man's attempts to tame it.

None of the three books gives us a clear answer. But the book by Clarfield and Wiecek, historians from the University of Missouri, strongly implies that we should abandon nuclear technology completely. This is a dangerous conclusion and unfortunately typical. Errors of fact in the book show that little reliance can be placed on the authors' justification of their case.

Clarfield and Wiecek consistently imply that military and civilian uses of nuclear

energy are inseparable and that we cannot stop one and not the other. This is a common view nowadays in the United States. But I regard as more tenable the proposition that military and civilian uses of nuclear power are separable and that world peace may depend on our ability to make the distinction clear. American anti-nuclear activists often damn bombs and power reactors equally; but the record shows that although activists have prevented many reactors from being built, it is doubtful whether they have reduced the military stockpiles by a single bomb. By pretending the two targets, bombs and power stations, to be equally dangerous, they have allowed themselves to be diverted from the military target and attacked the easier, more vulnerable, civilian target. Worse still, they have separated themselves from their natural allies in the scientific community and weakened the peace movement.

The layout of the book itself belies Clarfield and Wiecek's thesis. While the prologue and Chapter 1 are "mixed" chapters, about nuclear fission and its discovery, later chapters are *either* about bombs *or* about electric power reactors; not both. Only in the polemical epilogue do the two come together again.

In their discussion of nuclear safety, Clarfield and Wiecek tell their story from the outside looking in and would seem to be objective. But their technical discussions are simply wrong. Referring, as have other authors, to the Emergency Core Cooling Hearing of 1972–1973, they make the incorrect statement that "the AEC [Atomic Energy Commission] remained unmoved by these disclosures, and made no significant changes in its safety regulations". On the contrary, the AEC made enough changes to make the uncertainties disclosed in the hearing moot. The authors ignore the fact that tests of the emergency core cooling systems in 1978 showed that even the original criteria were conservative and had a margin of error.

Clarfield and Wiecek state that "Rasmussen actually had little to do with the substance" of the Reactor Safety Study of

Promising start: the Queen opens Calder Hall nuclear power station, October 17, 1956.

1975 of which he was in charge. This seems very unlikely; this year, the US Department of Energy awarded Rasmussen the Fermi Prize for his work. It is also untrue that "the Rasmussen report did not stand up well to criticism". On the contrary, the methodology is now almost universally used, and even critics rarely discuss reactor safety in any other framework. A recent study group of the American Physical Society gave it greater praise ten years later; it was found unnecessary to comment upon it specifically, but the results were used as a baseline with which to compare later calculations.

The several pages about the accident at Three Mile Island are particularly sloppy. The authors state that "the problems at TMI began when pumps forcing cooling water through the primary system tripped". It was the secondary, not the primary, pumps that tripped. The primary pumps were manually, and foolishly, shut down two and three-quarter hours later when they began to cavitate. The confusion between the primary and secondary systems is evident later in the same sentence when again they say that "temperatures began to rise in the core because the coolant was no longer flowing", clearly referring to the primary system, and then in the next sentence state that "this was a few seconds after the start of the accident". It was over two hours after the start of the accident that the primary system flow stopped and core heating really began.

More serious for a couple of historians is the uncritical mention of the worry of Dr Bridenbaugh about "the obvious use to which the government of India was putting its Tarapur reactor, the first 'peaceful' application of nuclear power in the Third World. The Indian government was reprocessing plutonium out of the spent fuel to build a bomb . . ."; this statement is almost certainly wrong. There is no evidence for it, and a lot of evidence against it. Tarapur and its fuel are under international safeguards and inspection. Both the Indian Government and the International Atomic Energy Agency say that the fuel has been stored, and the United States has a right in the agreement to take it back, unprocessed. More importantly, the reprocessed fuel would yield plutonium which has too much of the isotope ^{240}Pu , thereby making it unsuited for any but an unreliable bomb, and in India has other reactors of its own manufacture, not under safeguards, which are more suited to producing high quality, bomb grade, plutonium. Why should India break agreements and treaties, and risk being caught by an inspection, to get an inferior product?

In the second book under review, *Controlling the Atom*, I had hoped to find a clear description of the present regulations, how they led to the current situation, how France and Japan have avoided the problems, and how we might change

In defence of Martin Kamen: a cartoon in the *St Louis Star-Times*, September 4, 1948.

the situation by changing the regulations. The authors, Mazuzan and Walker, are historians at the Nuclear Regulatory Commission in Washington, and should be well equipped to do so. I do find a clear description of the present regulatory process in the United States although no comparison with its equivalents overseas. The problem arises because the book is strictly limited to the period 1946 to 1962, so that the failure of the industry in the past ten years is not even mentioned.

Nonetheless, this book makes interesting reading. The quotations make it clear that those who set up the regulatory procedures were as aware of the general safety problems as we are today. The book reminds us of the Brookhaven Study on catastrophic accidents which was presented to the Commission and released to Congress and the public on March 15, 1957, labelled WASH-740, and included the numerical estimates that some scientists gave to describe their "feeling" for the probability of accidents. Three estimates were given. Under the assumption of 100 operating reactors, and that 3,000 deaths would result from a major release outside the containment, one of them gave an individual risk of 1/50,000,000 per year of a person being killed by a reactor accident.

Eighteen years later, on February 21, 1985, I presented to the Nuclear Regulatory Commission a report prepared by a Study Group of the American Physical Society on "Radiological Consequences of Severe Nuclear Reactor Accidents". We concluded that an accident violating the containment is now much less probable than at the time of WASH-740 and although the reactors are bigger than anticipated in 1957, the consequences are likely to be smaller and 3,000 deaths would be very unlikely.

Thus it seems that the Brookhaven scientists were overly pessimistic. Although most of the American public were not interested and did not notice WASH-740 when it was released, the often-repeated

accusation that facts were withheld was, in general, untrue.

The book by Kamen, a distinguished chemist and co-discoverer of carbon-14, is a personal memoir. Kamen worked in the Radiation Laboratory at Berkeley from 1935 to 1944, and his book describes his early excitement as a scientist and his dismay at being dismissed from the Manhattan project in 1944.

It appeared later that his dismissal was not due to specific charges of disloyalty, but because he was a gregarious man with a wide circle of friends, some of whom were under suspicion. Kamen became more of a security risk than his usefulness to the project justified. Nonetheless he was denounced as "that atom spy" by the *Chicago Tribune* and *Washington Times-Herald*, but he won his libel suit against the one and the other settled out of court. His passport was withheld for seven years by Mrs Shipley, chief of the Passport Division of the US Department of State. The Department of Justice later stipulated that this was illegal. All this makes interesting reading and tells of how Americans can be misled by publicity hounds. But it also tells us another story. Bombs and power plants are only two of many uses of nuclear fission.

Kamen describes little of the scientific and technical work of the Manhattan Project in this book. It is clear that neither bombs nor electric power interest him. His scientific interests were other applications of nuclear science — first in isotopic tracers then cytochrome chemistry, biological oxidation, photosynthesis and protein structure. Radioactive isotopes in research and medical work are a third important use of nuclear fission in modern life. Kamen describes his excitement when he realized that some radioactive isotopes made for his work during the war were so radioactive that they must have been made by a nuclear reactor, rather than by a radium beryllium source. It was the medical applications of such work that earned Dr Rosalyn Yalow her Nobel Prize in medicine.

Small reactors have been built in a number of countries under the Atoms for Peace programme. It was a research reactor *not* a nuclear power reactor that was used by India to produce plutonium for a nuclear explosion. If we want to ban all nuclear technology in order to stop nuclear bombs, we would have to close down these research and isotope-producing reactors and thereby put an end to Kamen's and Yalow's research. The solution most of the world accepts is to allow both types of reactor to exist provided that there is international inspection under the Non-Proliferation Treaty. This is better than the chaos Clarfield and Wiecek would lead us to. □

Searching for their selves

Stuart Sutherland

The Man Who Mistook his Wife for a Hat. By Oliver Sacks. Duckworth: 1985. Pp.233. £9.95. To be published in the United States in January by Summit, \$15.95.

In his latest book, the author of *Awakenings* reports many curious happenings. Perhaps the most surprising is his revelation that one can be a practising neurologist without having read the literature on visual agnosia and without knowing that retrograde amnesia is common in Kors-

Oliver Sacks: unusual neurologist.

koff's psychosis, and indeed after medial temporal lobe damage in general. Oliver Sacks asserts that he only acquired the knowledge in question after having encountered such cases himself: it is of course possible, judging from *The Man Who Mistook His Wife for a Hat*, that he had been too busy reading Wittgenstein and Nietzsche to be bothered with the literature of his profession, but one fears he may be having the reader on, a suspicion that the remainder of his book does little to allay.

Dr Sacks recounts with verve and clarity some score of neurological case-histories, all of which make excellent short stories. He describes a wide range of symptoms, ranging from Tourette's syndrome, which is marked by tics, grimaces, curses, and "an odd elfish humour . . . and outlandish kinds of play", to those of an idiot savant. His cases have only two unusual features. First, they seem to present symptoms in an exceptionally pure form and do not exhibit the messy confounding of different syndromes so common in such patients. Second, they were treated by a very unusual neurologist, Dr Sacks himself.

He is unusual in that no matter how

devastating the incapacity caused by his patient's brain damage, he always seems able to locate, usually at the first interview, an area in which the patients' "self" is still intact and which they can be encouraged to develop. This may relieve their misery — where they are miserable, since many neurological patients have no understanding of their condition and may even be unnaturally cheerful. Moreover, the development of an intact interest or skill may, according to Sacks, help to alleviate patients' symptoms. He points, for example, to a mentally retarded girl with extremely clumsy body movements, whom he helped find herself through acting: when she was on the stage all her clumsiness disappeared.

Although Sacks's grasp of brain science seems at times a little shaky (for example, Wilder Penfield did not show "beyond doubt" that epileptic transports are direct

memories of the past rather than fantasies), his message is important and compassionate. He writes, "Our tests are ridiculously inadequate. They only show us defects . . . they do not show us a being conducting itself spontaneously in its own natural way". If we are to believe him, the discovery and promotion of the spontaneous self is particularly important in neurology, but it should surely play a role in all medicine.

The book deserves to be widely read whether for its message, or as an easy introduction to neurological symptoms, or simply as a collection of moving tales. The reader should, however, bring to it a little scepticism, for outside Sacks's clinic, things do not always fall out quite so pat. □

Different biology

Alan Bittles

Human Sexual Dimorphism. Edited by J. Ghesquiere, R.D. Martin and F. Newcombe. Taylor & Francis: 1985. Pp.375. £24, \$53.

ALTHOUGH, perhaps inevitably, there is considerable variation in the content and quality of the 18 contributions in a volume of this nature, based on a joint symposium organized by the Society for the Study of Human Biology and the European Anthropological Association, the editors have assembled an informative and very readable collection of papers on this important biological topic. From a purely semantic viewpoint, use of the term sexual dimorphism in the book is often somewhat inappropriate as the parameters can display considerable overlap between the sexes and show greater intra- than inter-group differences. The authors in general have adopted a fairly flexible, if occasionally rather arbitrary, definition for the expression of dimorphism in a species, and for this reason some of the conclusions may not necessarily be definitive.

Allometric analysis is used by a number of contributors in an attempt to unravel the circularity apparent in theories constructed to explain the origins of dimorphism. By scaling brain size to body size in simian primates it is apparent that dimorphism has evolved through reduced body size in females rather than increased male body size. Further, similar studies across a wide range of mammals have shown that brain weight is primarily associated with age at sexual maturity, rather than with lifespan as has been commonly supposed. Possible mechanisms governing embryonic sexual differentiation via H-Y antigen secreted by the Sertoli cells, and sex-differentiated behaviour

patterns are clearly presented. Given the difficulties inherent in obtaining experimental evidence from human studies, the elegant demonstration in zebra finches of a hormone-influenced dichotomous choice between male and female patterns at single neurone level, and the subsequent translation of the degree of brain masculinization into a behavioural continuum, may be of considerable significance.

While evidence from our hominid ancestors and the australopithecines relating to sexual dimorphism is both limited and literally fragmentary, the existence of dimorphic patterns in *Homo sapiens* is well established. As expected from the title, human sexual dimorphism is thoroughly assessed in a series of six papers on anthropometric, physiological and behavioural findings from a variety of extant populations in Europe, Africa and Asia. The possibility that apparent dimorphic differences may have arisen as a result of acculturation, rather than being representative of man's basal state, is illustrated in an extensive project conducted on Aboriginal hunter-gathers from Arnhem Land in northern Australia. Somewhat surprisingly, in this population the age-associated rise in blood pressure is a female, not a male, phenomenon which calls into question many of the assumptions made regarding the basic biology of our species, derived only from groups living in the developed countries.

Despite the less than perfect reproduction of the camera-ready format, overall this is an impressive publication which should find a ready audience across a wide range of biologists, behavioural scientists and clinicians. It can be recommended both as a source text and an interesting volume in its own right. □

Alan Bittles is Senior Lecturer in the Department of Anatomy and Human Biology, Kings College (KQC), University of London, London WC2R 2LS, UK.

Feeding and flocking

C.M. Lessells

Gulls and Plovers: The Ecology and Behaviour of Mixed-Species Feeding Groups. By C.J. Barnard and D.B.A. Thompson. Croom Helm/Columbia University Press: 1985. Pp.302. £25, \$30.

THE idea that natural selection can act on an animal's behaviour, as well as its more tangible characteristics such as morphology, is well established. Behaviour is not now merely described and measured but is interpreted in terms of the selection pressures responsible for its evolution and maintenance. Barnard and Thompson follow in this tradition with their study of lapwings, golden plovers and black-headed gulls feeding on worms in agricultural pasture.

At first sight, winter feeding and flocking behaviour are really rather mundane, but this book reveals the extent of the interdependence of feeding and flocking strategies within and between the three species: foraging choices of individuals determine the size and location of feeding flocks, while the composition of flocks in turn affects feeding rates and hence the best foraging strategies. To add to this, the black-headed gulls make their living by stealing worms from the plovers, while the plovers may exploit the gulls for early

warning of the approach of predators.

Clearly Barnard and Thompson have set themselves quite a task in unravelling the complexities of this system. Their quantitative approach to the problem relies on a wealth of data, so much so that the book is rather hard going. Ultimately the success of the book must be judged by whether they are able to cut a path through the jungle of tables and graphs.

As in many other studies, the difficulties firstly of assessing costs and benefits of alternative actions, and secondly of reconciling the different units (such as calories and probability of predation) of costs and benefits, have made quantitative predictions rather thin on the ground. Precise quantitative predictions, however, can be made about the choice of food items by feeding plovers and thieving gulls. The "optimal diet model" provides a well-worked solution to both problems, but here it has been mangled almost beyond

recognition. Profitability, encounter rate, availability and prey types are all incorrectly defined; for instance equation (8.2) is akin to saying that the overall effect of driving for a while at 20 mph and a while at 30 mph is driving at 50 mph. Consequently the line of argument is weakest where it should be strongest. Similarly, innovative thinking elsewhere in the book is marred by inadequate explanation, confused terminology or misused statistics.

Despite this there is much interesting new detail in the book and some new ways of looking at the interrelationships of flocking and foraging strategies. Barnard and Thompson would have contributed more, however, if in their genuine attempt to push back the frontiers of darkness they had not extinguished the lights behind them. □

Isolated objectives

C.J. Marshall

Molecular Cell Genetics. Edited by Michael M. Gottesman. Wiley: 1985. Pp.931. £82.30, \$79.95.

MUCH of the work on the genetics of cultured cells has made use of Chinese hamster cells, especially the CHO cell line originated by T.T. Puck, the founder of cell genetics. The importance of these cells is reflected in the emphasis of this book and it is worth noting that, as Yerganian describes, the use of Chinese hamsters is not without heroic and even tragic episodes — during the Revolution a Chinese research worker was imprisoned for his involvement in the shipment of animals to the United States.

The reasons why the CHO cell line has been used so extensively are partly historical, but perhaps more important is the comparative ease with which recessive phenotypes can be isolated in this cell line. Siminovitch, in 1976, proposed that recessive mutations could be isolated in CHO cells because some loci were hemizygous as a result of chromosome rearrangements.

Subsequent studies described by Siminovitch and others have confirmed and extended these ideas. For some autosomal loci, CHO does appear to have only one copy of the genes; however, other loci are diploid and there is increasing evidence that one locus can be inactivated or deleted by a high frequency event (10^{-3} or greater) to uncover recessive mutations. Such events may have profound implications for our understanding of alterations in gene activity that lead to neoplastic transformation.

In *Molecular Cell Genetics*, the editor lists over 100 mutant phenotypes in

Chinese hamster cells which include nutritional auxotrophic requirements, mutations in mitochondria, RNA polymerases, protein synthesis, DNA repair, lysosomes, membrane proteins, glycosylases, protein kinases and many others.

As is to be expected of a multi-authored book, the chapters in *Molecular Cell Genetics* are of variable quality. Some authors have written overviews of an area, often drawing very heavily on their own studies; others have provided both a review and useful hints for particular procedures. In most cases detailed experimental protocols are not provided, so this is not a laboratory manual but rather a source book which would enable one to find the appropriate protocol. Over half the chapters are concerned with particular mutant systems, while others describe features of Chinese hamster cells and methods for cell genetics such as cell fusion, gene transfer, and cloning and expression of cDNAs. Much of the work still appears to be at the stage of characterizing mutants rather than using them to dissect a particular system or probe the structural function of a protein.

For much of the book I felt that a great deal was expected of the next development: the isolation of the relevant genes. For some loci this has already been achieved; however, there is still much to be done before many of the mutant phenotypes can be exploited for what the editor terms "molecular cell genetics": the synthesis of somatic cell genetics with molecular biology.

For those working in this area, or thinking of entering it, this book will be a valuable source of information. They might like to bear in mind, however, that there is more to cell genetics than *Cricetulus griseus*. □

QUALITATIVE OBSERVATIONS ON RECENT FORAMINIFERAL TESTS . . .

WITH EMPHASIS ON THE EASTERN PACIFIC PARTS 1-111, 1977 — WITH EMPHASIS ON THE ATLANTIC, PART IV, 1981

by Irene A. McCulloch, PhD

This monographic work, in preparation for more than 30 years, consists of three parts on the Pacific, totalling more than 1000 pages with 200 folio-sized plates and covering some 360 genera and 2,300 species. Part IV on the Atlantic consists of 361 pages with 72 folio-sized plates covering more than 700 taxa. The folio-sized volumes are on 50% rag paper, bound in durable dark red Buksyn with gold stamped covers.

These collectors items normally sell for \$200 per set, but in honor of Dr. McCulloch's 100th Birthday we are offering them for \$100 per set.

California residents add sales tax; Domestic order add \$10; Foreign add \$16 for handling.

Make checks or money orders payable in dollars to the Irene McCulloch Fund.

Leukocyte Typing II

Editors: **E. L. Reinherz**, Boston, MA; **B. F. Haynes**, Durham, NC; **L. M. Nadler**, Boston, MA;
I. D. Bernstein, Seattle, WA

Leukocyte Typing II summarizes the results of the Second International Workshop on Human Leukocyte Differentiation Antigens. This effort involved all research groups active in the field of human leukocyte antigens defined by monoclonal antibodies. This extraordinarily broad-based study was sponsored by NIH, WHO, and IUIS. The results of this analysis will be the basis for recommendations regarding standardization and nomenclature on workshop results.

The three volumes deal with the technical details of the surveys of monoclonal antibodies directed at T lymphocytes, B lymphocytes, and myeloid

and other hematopoietic precursor cells. Technologies involving fluorescence-activated cell sorting techniques, biochemistry of cell surface glycoproteins and glycolipids, as well as functional studies with peripheral blood lymphocytes and T cell clones are described. This compendium is indispensable to the research immunologist, clinical immunologist, hematologist and oncologist. In addition, it reviews the rapid progress that has been made in these fields over the last several years, thus providing a clear guide for the nonspecialist who wishes to be brought up to date with human immunology.

Complete in 3 volumes, each volume also available separately.

1. Human T Lymphocytes

1986. 123 figures, 171 tables. Approx. 600 pages
Hard cover DM 240,-. ISBN 3-540-96175-5

Contents: Summary of T Cell Studies Performed During the Second International Workshop and Conference on Human Leukocyte Differentiation Antigens. - Functional Studies. - Biochemical Studies. - Phenotypic Characterization of T Cell Leukemias and Lymphomas. - Phylogenetic Studies of T Cell Antibodies. - Study of Anti-T Cell Antibodies on Frozen Tissue Section of Human Tissue. - Study of Antibodies Reactive with Antigens of Activated T Cells. - Study of T Cell Leukemia-Associated Antigens. - Other Types of Studies and Description of New T Cell Markers.

2. Human B Lymphocytes

1986. 134 figures, 171 tables. Approx. 600 pages
Hard cover DM 220,-. ISBN 3-540-96176-3

Contents: Introductory chapter by L. Nadler. - Biochemical analysis of antigens defined by the workshop B cell/leukemia panel. - Immunohistochemical analysis of B cell/leukemia panel monoclonal antibodies. - Expression of B cell/leukemia panel on leukemias and lymphomas. - Functional significance of human B cell/leukemia antigens.

3. Human Myeloid and Hematopoietic Cells

1986. 66 figures, 121 tables. Approx. 415 pages
Hard cover DM 178,-. ISBN 3-540-96177-1

Contents: Joint Report of the Myeloid Section of the Second International Workshop on Human Leukocyte Differentiation Antigens. Serological, Biochemical and Cytogenetic Studies with the Granulocyte Monoclonal Antibodies of the 'M Protocol'. - Functional Studies with Monoclonal Antibodies Against Function-Associated-Leukocyte Antigens. - Monoclonal Antibodies that Identify Mol and LFA-1. Two Human Leukocyte Membrane Glycoproteins: A Review. - Reactivity Patterns of Monoclonal Antibodies Against Myeloid-Associated Antigens with Human Natural Killer Cells. - A Map of the Cell Surface Antigens Expressed on Resting and Activated Human Natural Killer Cells. - Study of the Antigenic Profile of Normal Myelomonocytic Progenitors and Leukaemic Cell Lines Using Monoclonal Antibodies. - Immunohistochemical Reactivity of Anti Myeloid/Stem Cells Workshop Monoclonal Antibodies in Thymus, Lymph Node, Lung, Liver and Normal Skin. - Immunohistological Characterization of Myeloid and Leukaemia-Associated Monoclonal Antibodies. - Antigens Analysis of Human Malignant Myeloid Cells by Immunoperoxidase. - Expression of Lymphocyte Antigens on Blast Cells from Patients with Chronic Granulocytic Leukemia. - Different Stages of T Cell Differentiation and Microenvironments in the Thymus as Defined by Immunohistology.

nature FIRST CONFERENCE IN JAPAN

◎ January 20 ⇒ 22, 1986

◎ Keio Plaza Hotel, Tokyo, Japan

Nature is pleased to announce a conference on the future of molecular biology and its applications in biotechnology and medicine, to be held at the **Keio Plaza Hotel, Tokyo**, on **January 20-22, 1986**. The conference will be addressed by distinguished molecular biologists from the United States, Europe and Japan.

The speakers from the United States will include Nobel Prize winners **James D. Watson** (*Cold Spring Harbor*), who (with F.H.C. Crick) first suggested the structure of DNA, and **Walter Gilbert** (*Harvard University*). Other speakers include: **Stanley Cohen** (*Stanford University*), **Tom Blundell** (*Birkbeck College, London*), **W.J. Peacock** (*CSIRO, Canberra*).

Walter Gehring (*University of Basel*)

Richard Lerner (*Scripps Clinic, La Jolla*)

Sydney Brenner (*Laboratory of Molecular Biology, Cambridge*)

Susumu Tonegawa (*Massachusetts Institute of Technology*)

Shosaku Numa (*Kyoto University*)

Tasuku Honjo (*Kyoto University*)

Ken-ichi Matsubara (*Osaka University*)

Yoshiki Hotta (*University of Tokyo*)

Mitsuaki Yoshida (*Cancer Research Institute*)

Tadatsugu Taniguchi (*Osaka University*)

Hisayuki Matsuo (*Miyazaki Medical College*)

Tokino Okada (*National Institute for Basic Biology*)

Hal Weintraub (*Hutchinson Cancer Center, Seattle*)

The three main topics to be covered by the conference are

- Molecular biotechnology
- Development and regulation
- Immunology and virology

and the programme is being designed to provide an opportunity for those working in industry, medicine or academic research to bring themselves up to the forefront of research through discussion with world leaders. There will be ample time for questions and discussion. Simultaneous translation services into English and Japanese will be available.

Registration fees:
¥100,000

Full details are available from **Nature Conference Secretariat International Conference Organizers, Inc.**

MOLECULAR BIOLOGY BECOMES BIOTECHNOLOGY

Localizing active sites in zeolitic catalysts: neutron powder profile analysis and computer simulation of deuteropyridine bound to gallozeolite-L

Paul A. Wright*, John M. Thomas*, Anthony K. Cheetham^{†‡} & Andreas K. Nowak[†]

* Department of Physical Chemistry, University of Cambridge, Lensfield Road, Cambridge CB2 1EP, UK

[†] Chemical Crystallography Laboratory, University of Oxford, Parks Road, Oxford OX1 3PD, UK

The location of a guest organic base within a model zeolitic catalyst can be quantitatively determined from an analysis of the neutron powder diffraction profile. The calculated position and orientation of the guest species within the channel agree well with the experimental values.

THE analogy between the mode of action of enzyme catalysts and zeolites is more than superficial. In each case, folds or cavities in the catalysts impose shape-selectivity that governs the 'choice' of reactant species, and the molecular complementarity of the microenvironment of the active site facilitates ensuing chemical conversion. Paradoxically, progress in characterizing the nature of active sites in enzymes (and, therefore, in engineering new proteins^{1,2}) is more advanced than that in characterizing the precise nature of the active site in zeolites. Notwithstanding their greater molecular complexity, enzymes can be made to yield good-quality single crystals which are then amenable to X-ray crystallographic analyses. Moreover, since the advent of genetic engineering, theories of enzyme catalysis in general, and views about active sites in particular, can be tested by delicate alteration of the enzyme structure. With zeolites, however, the situation is rather different. Although rapid progress has recently been made in the synthesis of new zeolitic catalysts³⁻⁵, it is very difficult to prepare them as defect-free, single crystals of a size and quality that permits X-ray analysis of the reactant-catalyst complex. Consequently, it has not yet been possible to emulate, using aluminosilicate zeolitic catalysts, work such as that done to locate fructose-6-phosphate and ATP at the active site of fructophosphokinase^{1,2}.

Alternative approaches to the elucidation of the structure of zeolitic catalysts have, therefore, been evolved⁶⁻²². These include application of such techniques as high-resolution electron microscopy⁶⁻¹¹, atom-atom calculations^{12,13}, magic-angle spinning NMR (MAS-NMR)¹⁴⁻¹⁷, and neutron¹⁸⁻²² and X-ray^{23,24} powder profile analysis. Of these techniques, the neutron profile method yields quantitative atomic structural information; it has been used to determine the location of the detachable proton in the (Brønsted)-active site in La³⁺ ion-exchanged zeolite-Y catalyst²¹, and also the siting of guest species such as Xe (which serves as a model for methane) in zeolite-rho²², and CO in zeolite-A²⁵. The precise location of sorbed benzene in zeolite-Y has also been determined by neutron powder profile analysis²⁶. Here we identify in atomic detail the siting of pyridine (which, together with other nitrogenous bases such as 4-methylquinoline²⁷, is used to block active sites) in the channels of a synthetic zeolite-L, and compare our results with a computer simulation based on atom-atom potentials.

Neutron powder diffraction analysis

The particular catalyst preparation used is a potassium salt of a gallosilicate-L, in which Ga replaces Al in the well-known structure (Fig. 1) of the anion framework²⁸. Chemical analysis gave a unit cell composition of K_{10.3}Ga_{10.3}Si_{25.7}O₇₂ for the dehy-

Fig. 1 A schematic representation of the structure of potassium zeolite-L, viewed down [001]. The aluminosilicate framework is indicated by lines and the cation positions as small circles. The large channel runs parallel to [001].

drated sample. Samples were characterized by X-ray diffraction and by MAS-NMR. High-quality, microcrystalline samples of the potassium salt (henceforth designated KGaL) yielded good neutron diffraction (powder) patterns, both in the dehydrated state and after incorporation into the dehydrated solid of ~1.2 molecules of perdeuteropyridine per unit cell. Data were recorded at 4 K at the Institut Laue-Langevin (ILL), Grenoble, using the high-resolution powder diffractometer, D1A.

There were some 70 discernible peaks in the 2θ -range with a neutron wavelength of 1.909 Å. Refinement of the structure, using Rietveld profile analysis^{18,19}, was done as follows. First, the starting coordinates of a previous refinement of KAIL²⁸ were assumed for the KGaL. Scattering lengths were taken from Bacon²⁹: $b_O = 0.575$, $b_N = 0.940$, $b_C = 0.663$, $b_K = 0.37$, $b_D = 0.67$, all in units of 10^{-14} m. The scattering of the tetrahedral sites was calculated from a weighted average of the scattering lengths of silicon ($b_{Si} = 0.415$) and gallium ($b_{Ga} = 0.720$) and the occupancies refined. Refinement progressed smoothly; the occupancy factors of the two distinct tetrahedral sites were

varied independently, but they showed no evidence of Ga/Si ordering of the kind found in zeolite-A²⁰ for the Si/Al tetrahedral sites. The K⁺ ions in KGaL are located in precisely the sites that they occupy in KAlL²⁸. The final profile (R_p) and weighted profile (R_w) values were 7.5% and 8.3% respectively. Structural details are given in Tables 1A and 2.

Initial refinement of the data for the perdeuteropyridine complex was carried out using the model for KGaL, and a difference Fourier calculation showed that there was appreciable scattering from within the main channels. Recognizing (from infrared evidence³⁰) that the nitrogen of the pyridine is sited close to a K⁺ ion, and that the pyridine probably retains its planarity and other structural features of the free molecule, several model structures were generated—first with the plane of the pyridine initially parallel to (010), then parallel to (001) and to several other angles of tilt with the molecule parallel to (001). A model with the molecule tilted 24° with respect to (010) refined to high occupancy and yielded an encouraging improvement in R_w . Continuing in this manner, and allowing the K-4 site of potassium and framework sites to relax, while retaining N-1, C-3 and D-3 on the (001) mirror plane, a refinement (with an R_p and R_w of 11.3% and 12.00% respectively) was obtained indicating 1.5 molecules of pyridine per unit cell (Fig. 2). At all stages, the pyridine was constrained to the structure of the free molecule³¹. Attempts to refine the structure with the molecule

* In the literature there is talk of another site for the potassium ion, labelled K-1, for which we find no evidence in this study.

placed at other positions, for example as a π complex with K-4, gave a substantially higher R factor ($R_p = 15.5\%$). The final observed and calculated profiles for both KGaL and the zeolite-pyridine complex are shown in Fig. 2. The structural details are given in Tables 1B and 2.

Figure 3A shows the location of a single pyridine molecule in the main channel of zeolite-L. The nitrogen atom is coordinated to potassium, K-4, but the molecule also lies close to the channel wall, thus optimizing its interaction with the zeolite framework. On general chemical principles, coordination of alkali metals by ammine ligands is rare; but clearly the open, 6-fold coordination of K-4 in this dehydrated system offers an attractive location for the basic pyridine molecule. The observed K—N distance, 3.00 (± 0.03) Å, is consistent with metal—nitrogen distances found in amines of NaCl (Na—N ~ 2.6 Å³²).

A comparison of our two refinements shows that the framework structure of the zeolite appears to be essentially unperturbed by the presence of the pyridine molecule, but this conclusion may be misleading because, on average, only 1.5 of the six potassium sites K-4 in each cavity are coordinated. Only a fraction of the framework atoms around the channel will therefore respond to the close proximity of pyridine. However, the position of K-4 does appear to have altered slightly on complexation with the pyridine.

Computer simulation

We have also explored the possibility of calculating the minimum energy position for pyridine in zeolite-L, using atom-atom potentials according to the method of Ramdas *et al.*³³. Kiselev, whose parameterization was used in the present work, has already shown^{34,35} that such calculations yield enthalpies of adsorption that are in good agreement with experimental data. We used the program 'Chemgraf'³⁶. The calculation models the short-range (van der Waals) interactions and the electrostatic terms (dipolar and higher order, in this instance) between the pyridine and the zeolite, but it does not include any covalent contribution to the K—N bond energy—this, of course, is expected to be small. A single molecule was placed as in Fig. 3A and the interaction energy was calculated as a function of its

Fig. 2 Neutron powder diffraction profiles of *A*, KGaL and *B*, the KGaL-perdeuteropyridine complex. The upper curves show the observed and calculated profiles—these are generally coincident within the resolution of the plotter. The lower curve shows the difference profile. The vertical lines mark the peaks used in refinement (up to 2θ of 120°).

Fig. 3 *A*, The location of a single pyridine molecule in the large channel of zeolite-L, viewed approximately down [001]. *B*, A view of the pyridine molecule down [001], showing the angle θ which was varied for the calculations shown in Fig. 4A.

Fig. 4 The interaction energy between pyridine and the zeolite as a function of (*A*) the angle θ and (*B*) the K-4—N distance at $\theta = 8.8^\circ$; the observed positions are indicated by dashed lines.

angular position θ (Figure 3*B*) and the K-4—N distance at $\theta = 8.8^\circ$; the calculations yield an energy minimum at this θ value (Fig. 4*A*) that is in excellent agreement with the observed value of 8.6° , and a K-4—N distance of 3.13 \AA (Fig. 4*B*). The predicted position of the molecule is within 0.2 \AA of the observed location.

Discussion

It is worthwhile emphasizing that exclusive occupancy of the minimum enthalpy position of the molecule is likely to be found only at very low temperatures, as used in the present work, where entropy considerations are minimized. This factor underlines one of the great advantages of powder neutron diffraction methods—the ease with which data can be collected over a wide temperature range. The concordance between our experimental and theoretical results lends credence to the efficacy of both methods, and more ambitious aims may now be within reach. These include the simulation of catalytic reactions in zeolites, by using a combination of molecular mechanics and molecular orbital calculations, the experimental location of catalytic intermediates, and—again drawing on the enzyme analogy—the study of sorbate motion in zeolites by molecular dynamics.

New constraints on transient lower mantle rheology and internal mantle buoyancy from glacial rebound data

W. R. Peltier

Department of Physics, University of Toronto, Toronto, Ontario, Canada M5S 1A7

A model of mantle rheology which has an explicit transient component of its relaxation spectrum is shown to reconcile two apparently conflicting inferences of lower mantle viscosity. If recent analyses of isostatic geoid anomalies are correct in requiring a large increase of viscosity with depth, then the weak viscosity stratification demanded by postglacial rebound data implies the importance of such rheological behaviour, at least in the Earth's lower mantle.

OVER the past decade a large number of diverse geophysical observations have been shown to be intimately connected with the process of glacial isostatic adjustment. These include relative sea-level histories in the age range 0-18 kyr before present, free-air gravity anomalies over existing centres of postglacial rebound, and certain anomalies in the Earth's rotation including the non-tidal component of acceleration of the axial rotation rate which has recently been confirmed (through J_2) by laser ranging to the LAGEOS satellite^{1,2}, and the wander of the rotation pole with respect to the surface geography which is revealed in the International Latitude Service path to be occurring at a rate near (0.95 ± 0.15) degrees per 10^6 yr towards eastern Canada.

The demonstration of the intimate connection which exists between these phenomena has been provided through systematic application of the linear viscoelastic field theory of glacial isostasy³. Detailed recent accounts of the application of this theory to the four types of data mentioned above have appeared in several recent articles⁴⁻⁷. All of the analyses described in these papers were predicated on the assumption that the mantle could be described as a linear Maxwell solid insofar as its viscoelastic behaviour was concerned. The main result of these analyses has been the demonstration that in the context of this rheological parameterization, the viscosity of the mantle had to be rather uniform, with a lower mantle value of $2-3 \times 10^{21}$ Pa s and an upper mantle value close to 10^{21} Pa s. Furthermore, relative sea-level data from beyond the margin of the Laurentian ice sheet can be invoked⁸ to constrain the thickness of the continental lithosphere to a value near 200 km, and several articles^{5,7,9} have established that in order to explain observed free air gravity anomalies with the same model as is required to fit sea-level observations, the internal density stratification of the mantle must be allowed to deliver a buoyant restoring force when the individual horizons within it are deflected from their equilibrium levels in the isostatic adjustment process. This latter inference is obviously of interest from the point of view of theories of the mantle convection process.

Transient rheology and glacial isostasy

Weertman¹⁰ first drew attention to the possibility of a conflict between the uniform viscosity mantle implied by glacial rebound

data and the highly non-uniform viscosity mantle expected on the basis of the microphysical theory of solid-state creep in the Earth. He suggested that the resolution of this impasse may be simply to allow that the lower mantle viscosity to which the rebound process was sensitive is a transient value rather than the steady-state value which is assumed in the Maxwell analogue. Until recently it has remained equally plausible that the fundamental assumptions underlying the microphysical model might be the cause of the discrepancy between the expected value of the lower mantle viscosity and that required by glacial rebound observations.

Recent analyses of isostatic geoid anomalies by Hager¹¹ and Richards and Hager¹² appear to point to the validity of Weertman's interpretation, however, because these anomalies, presumably forced by the density heterogeneity associated with mantle convection, are interrogating the viscosity spectrum on a characteristic timescale of the order of 10^8 yrs. Richards and Hager found that they could fit the lowest degree components of the geoid height spectrum ($l=2$ and $l=3$) on the basis of the internal heterogeneity of density inferred from seismic tomographic analyses^{13,14} only if the lower mantle were about a factor of 10 more viscous than the upper mantle. Given the simplicity of the model used to make this inference, the increase in the viscosity contrast preferred by the longest wavelength geoid height data above that required by glacial rebound observations may or may not be significant.

In order to obtain a similar reconciliation of geoid height anomalies in the spectral range $4 \leq l \leq 9$, however, Richards and Hager were obliged to add the lateral heterogeneity of density associated with downgoing slabs in oceanic subduction zones to that supplied by objective seismic tomography, since the latter technique is as yet insensitive to these smaller wavelength features when applied on a global basis. To best fit the pattern and amplitude of the slab scale geoid height features then required a very substantial further increase in the contrast of viscosity between upper and lower mantle. Recently stated preferences for the contrast have reached a factor of 10^2 or more. In this article I wish to point out an important implication of this result, if it is in fact correct, and to demonstrate through explicit analysis the way in which it would have to be reconciled with previous work on the problem of glacial

isostatic adjustment if it should be verified by further investigation.

There have in fact been several recent re-analyses of post-glacial rebound phenomena, inspired in part by this result, using a rheological parameterization which explicitly includes transient relaxation of the lower mantle as was suggested originally by Weertman¹⁰ to be necessary on other grounds. If such additional rheological complexity were manifest it would clearly explain in a rather simple way why the viscosity of the lower mantle 'seen' by short timescale glacial rebound phenomena might be significantly lower than the viscosity controlling the longer timescale mantle convection process. The Burgher's body model of Peltier *et al.*¹⁵ has recently been used by several authors¹⁶⁻¹⁸ to represent the hypothesized lower mantle transient. The main conclusion derived from this work is that such models might provide equally acceptable fits to the data as those previously delivered by the Maxwell models in which the relaxation spectrum contains no transient component. In this article I demonstrate that, when all of the signatures of the isostatic adjustment process are invoked simultaneously, it is possible to restrict very considerably the class of such transient models allowed by the data. In particular it will be demonstrated that acceptable models in the allowed class are those which essentially behave as Maxwell models and that strong internal buoyancy is still required within the mantle if they are to reconcile simultaneously both relative sea-level and free-air gravity observations.

Burgher's body rheology

The frequency-dependent shear modulus of a three-dimensional Burgher's body rheology has the form¹⁵:

$$\mu(s) = \frac{\mu_1 s}{(s + \mu_1/\nu_1)} \left[\frac{(s + \mu_2/\nu_2)(s + \mu_1/\nu_1)}{(s + \mu_2/\nu_2)(s + \mu_1/\nu_1) + \mu_1 s/\nu_2} \right] \quad (1)$$

in which s is the Laplace transform variable, μ_1 is the elastic shear modulus, ν_1 the steady-state viscosity, and μ_2 and ν_2 are the shear modulus and viscosity of the Kelvin-Voigt element of the Burgher's body which determine the strength and timescale of the transient relaxation which it supports. Note from equation (1) that in the limit $\nu_2 \rightarrow \infty$ the Burgher's body degenerates to a Maxwell solid with $\mu(s) = \mu_1 s / (s + \mu_1/\nu_1)$ which is the same analogue as has been conventionally used in postglacial rebound analyses³. More important for our present purposes is the limit $\mu_2 \rightarrow 0$ in which case the analogue again degenerates to a Maxwell solid but in this limit $\mu(s) = \mu_1 s / (s + \mu_1/\nu_{\text{eff}})$ where the effective viscosity $\nu_{\text{eff}} = \nu_1 \nu_2 / (\nu_1 + \nu_2)$. This is important because it means that in the limit of large defect ($\mu_2 \ll \mu_1$) the relaxation will proceed as if it were a steady-state relaxation, and to the extent that $\nu_1 \gg \nu_2$ the effective viscosity governing the rate at which relaxation proceeds will be the transient viscosity since $\nu_{\text{eff}} \approx \nu_2$ in this limit. This article addresses the question of whether transient rheologies which have only modest elastic defect, for which the condition $\mu_2 \ll \mu_1$ does not apply, are viable models for the explanation of isostatic adjustment data. The results presented below demonstrate that they are not and therefore that previous inferences of effective lower mantle viscosity based upon application of the Maxwell analogue may simply be interpreted as representing a transient element of the viscosity spectrum if this should prove necessary. Although transient models which are allowed by the data are able to fit free-air gravity observations with somewhat less internal mantle buoyancy than was required with the Maxwell analogue, non-negligible buoyancy is still required.

For purposes of the present discussion we will assume that only the lower mantle has a transient component in its relaxation spectrum and therefore will take $\nu_2 = \infty$ in the upper mantle over the depth range 0-670 km. This is not meant to imply that transient relaxation of the upper mantle can be excluded on any *a priori* grounds but only that we intend to illustrate the influence of transient rheology in terms of a model in which its effect is confined to the lower mantle. We will also assume that the steady-state viscosity of the upper mantle is 10^{21} Pa s and

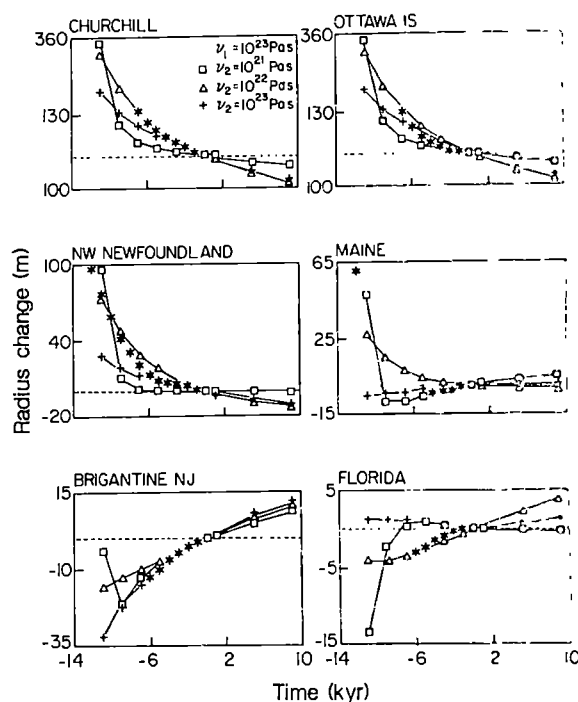

Fig. 1 Comparison of observed (*) and predicted relative sea-level data at six North American sites for the Burgher's body rheology with $\mu_2/\mu_1 = 0.1$. The lithospheric thickness of the Burgher's body is fixed at 120.7 km, $\nu_1 = 10^{21}$ Pa s and $\nu_2 = \infty$ in the upper mantle, and $\nu_1 = 10^{23}$ Pa s in the lower mantle. The different relative sea-level predictions on each plate are for models with lower-mantle ν_2 values of: 10^{21} Pa s (\square), 10^{22} Pa s (\triangle), 10^{23} Pa s (+).

the lithospheric thickness 120.7 km. Between the seismic discontinuity at 670 km depth and the core-mantle boundary, we will, for purposes of illustration, accept the results of Richards and Hager¹² as fixing the steady-state creep resistance of the lower mantle to the value of 10^{23} Pa s, that is, two orders of magnitude higher than the upper mantle value. We will then invoke the four previously discussed signatures of the isostatic adjustment process to constrain the remaining parameters μ_2 and ν_2 which are required to complete the description of the rheology of the lower mantle. The elastic structure upon which the above viscous layering is superimposed will be assumed identical to the model with two internal mantle density discontinuities which I have used previously⁸ which as a 3.8% increase of density at 420 km depth and a 6.2% increase at 670 km depth. In the analysis of free-air gravity anomalies we will compare the predictions of this model to one which has no internal mantle density discontinuities and therefore no source of internal mantle buoyancy.

Transient relaxation and postglacial rebound

Figure 1 shows observed and predicted relative sea-level variations at six North American sites for the Burgher's body rheology with $\mu_2/\mu_1 = 0.1$ and for three different choices of the lower mantle ν_2 ($=10^{21}$ Pa s, 10^{22} Pa s and 10^{23} Pa s) with other parameters of the model fixed to the values stated above. All calculations are based upon the circular disk load approximation to the Laurentian ice sheet with parameters listed in ref. 8 and include the influence of seven prior 10^5 -yr cycles of glaciation and deglaciation as may be inferred to have occurred on the basis of $\delta^{18}\text{O}$ data from deep-sea sedimentary cores. Inspection of these comparisons demonstrates that at sites within the ice sheet margin like Churchill, Ottawa Islands, and north-west Newfoundland, the data prefer 10^{21} Pa s $< \nu_2 < 10^{22}$ Pa s with the lowest value strongly rejected because it leads to overly rapid initial relaxation and thus severely underestimates present day emergence rates. More detailed analysis demonstrates that the preferred ν_2 at Churchill is 5×10^{21} Pa s, whereas that at both the Ottawa Islands and north-west Newfoundland sites is closer to $2-3 \times 10^{21}$ Pa s. At the Maine site which is on the ancient

Fig. 2 Predicted J_2 and the associated non-tidal acceleration of rotation as a function of lower-mantle viscosity for both the Burgher's body rheologies with $\mu_2/\mu_1 = (0.1, 0.01)$ and for the Maxwell analogue to which the Burgher's body degenerates in the limit $\mu_2 \rightarrow 0$. The upper and lower horizontal dashed lines on this plate correspond respectively to the observed values based upon the analyses of Lageos data by Yoder *et al.*¹ and Rubincam².

margin of the Laurentian ice sheet, high values of ν_2 eliminate the non-monotonic signature from the predictions and therefore are excluded by the data. As was found to be the case with the Maxwell analogue, even a value of 5×10^{21} Pa s for lower mantle ν_2 is unacceptable from the point of view of such data. At Brigantine further south (see ref. 8 for a location map) the data are not as sensitive to lower-mantle viscosity. As shown previously⁸, however, the observations at such sites which are near the crest of the glacial forebulge are extremely sensitive to lithospheric thickness. The fact that we are able to fit the observations at this site with a model that has a lithospheric thickness of 120.7 km suggests that thinner lithospheres may be allowed in models which include lower-mantle transient relaxation.

Further south at Florida the observations do require some elevation of lower-mantle viscosity in order to eliminate the prediction of raised beaches which would otherwise obtain. This is also in accord with results obtained with the Maxwell model¹⁸ and detailed analysis for a wide range of ν_2 values demonstrates that a value of $\nu_2 \approx 3 \times 10^{21}$ Pa s is sufficient for this purpose as well as being allowed by the observations at edge sites like Maine. The main result implied by these analyses of relative sea-level data is the demonstration that the transient Burgher's body model can reconcile glacial isostatic adjustment data to a certain extent, and if $\mu_2/\mu_1 = 0.1$ the model is already behaving very similarly to the Maxwell model, since the lower-mantle value of ν_2 inferred by fitting the model to the data has the same value ($\sim 3 \times 10^{21}$ Pa s) as was previously inferred for ν_1 in the context of the Maxwell analogue. It is rather more difficult to fit all relative sea-level data with the same Burgher's body model than has previously been shown to be the case with the Maxwell model, however, and, as we will proceed to demonstrate, even the small value of $\mu_2/\mu_1 = 0.1$ is too large to accommodate the remaining signatures of the rebound process.

Figure 2 shows observed and predicted J_2 for the three-disk load approximation to the deglaciation history which is detailed in ref. 6, and which contains about 100 m of mean sea-level variation between successive glacial maxima and minima. Again the calculations are based upon the assumption that seven previous 10^5 -yr cycles of glaciation and deglaciation have occurred. The upper horizontal dashed lines on Fig. 2 denote the bounds on J_2 recently inferred by Yoder *et al.*¹, whereas the

Fig. 3 Predicted polar wander speed as a function of lower-mantle viscosity for the Burgher's body rheologies with $\mu_2/\mu_1 = (0.1, 0.01)$ in which case the lower-mantle viscosity varied as the transient value ν_2 , and for the Maxwell model to which the Burgher's body degenerates in the limit $\mu_2 \rightarrow 0$ in which case the lower-mantle viscosity varied is the steady-state value ν_1 . The solid curves on this figure are predictions for models with lithospheric thickness 120.7 km while the dashed curves are the predictions of models with lithospheric thickness of 95.8 km.

lower lines denote the bounds on the same observations by Rubincam². Predictions are shown as a function of lower-mantle viscosity for three different models. The first model is the Maxwell model which I have used in previous analyses of this datum and the lower-mantle viscosity varied in these calculations is therefore the steady-state viscosity ν_1 . The second and third models are Burgher's body analogues with $\mu_2/\mu_1 = 0.1$ and 0.01 and the lower-mantle viscosity varied in these calculations is the transient viscosity ν_2 since the steady-state value ν_1 is fixed to the value of 10^{23} Pa s on the basis of the results of Richards and Hager¹². As pointed out in ref. 19, the J_2 observation is an especially important one because it is relatively insensitive both to the amount of internal buoyancy in the mantle and to the thickness of the lithosphere. It should therefore deliver a particularly unambiguous constraint upon the contrast in viscosity between the upper and lower mantle. Insofar as the J_2 observation is concerned, the ratio $\mu_2/\mu_1 = 0.1$ is still too large for the Burgher's body to have degenerated to an equivalent Maxwell solid. For $\mu_2/\mu_1 = 0.01$, however, the predictions of the Burgher's body as a function of lower-mantle ν_2 are very close to the predictions of the Maxwell solid as a function of lower mantle ν_1 . Most important, however, in the fact that with $\mu_2/\mu_1 = 0.1$ the lower-mantle value of ν_2 must be near 10^{22} Pa s in order to fit the observed J_2 . This is not compatible with the requirements of the sea-level data discussed previously (particularly those at edge sites like Maine), so that in the context of the Burgher's body $\mu_2/\mu_1 \ll 0.1$ seems to be required. Only if the transient model satisfies the asymptotic condition and thus acts effectively as a Maxwell model is such a model acceptable. This is further confirmed by the second rotational datum.

Figure 3 shows an analogous comparison to that in Fig. 2 but for the speed of polar wander predicted by the three ice cap model⁶. As discussed elsewhere^{6,7}, this is a particularly intricate calculation to perform as the forced polar wander involves a complex interplay between rotational and isostatic adjustment effects. The horizontal dashed lines on Fig. 3 represent the observed speed of polar wander of 0.95 ± 0.15 deg per 10^6 yr. The predicted polar wander direction does not depend at all on the rheology⁶. Also shown for comparison purposes, are results for the two Burgher's body rheologies with a reduced lithospheric thickness of 95.6 km which are shown as the dashed line.

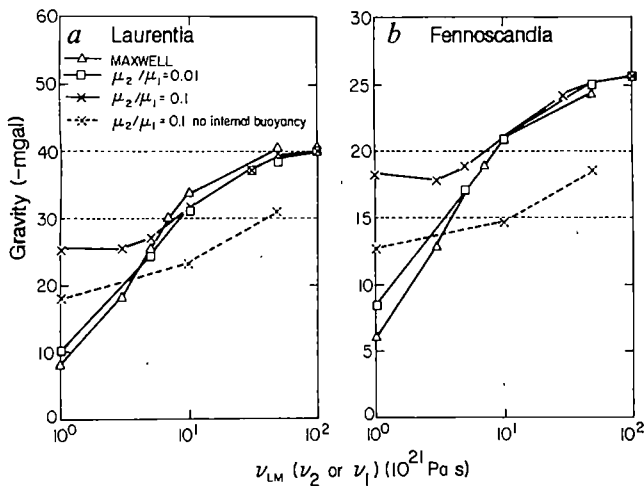

Fig. 4 Predicted peak free-air gravity anomalies at the centres of Laurentia (a) and Fennoscandia (b) as a function of lower-mantle viscosity in the Burgher's bodies with $\mu_2/\mu_1 = (0.1, 0.01)$ in which cases the lower-mantle viscosity varied as the transient value ν_2 , and in the Maxwell analogue to which the Burgher's body converges in the limit $\mu_2 \rightarrow 0$, in which case the lower-mantle viscosity varied as the steady-state value ν_1 . The elastic basic state used in these calculations is the one in which there are density increases of 3.8% and 6.2% at 420 km and 670 km depth respectively. Also shown on these separate plates for the dashed lines are the predicted free-air gravity anomalies for the Burgher's body analogue with $\mu_2/\mu_1 = 0.1$ using an elastic basic state in which the mantle contains no internal buoyancy. Clearly, even in the Burgher's body case considerable internal buoyancy appears to be required to fit the observed free-air anomalies but perhaps somewhat less than for the Maxwell model.

Again, the results for $\mu_2/\mu_1 = 0.01$ are close to the predictions of the Maxwell model to which the Burgher's body degenerates in the limit $\mu_2 \rightarrow 0$. For the transient model with $\mu_2/\mu_1 = 0.1$, however, the polar wander speed is sharply reduced, so much so that it cannot match the observation whatever the value of lower-mantle ν_2 . Indeed, only for the high contrast model with $\nu_2 = 10^{22}$ Pa s is it barely within a standard error of the observed speed of 0.95 deg. per 10^6 yr. This datum also requires large viscosity contrast with $\mu_2/\mu_1 = 0.1$, if it can fit the data at all, and therefore is ruled out by the sea-level data, particularly those at edge sites which display a non-monotonic history of postglacial sea-level variation. The predictions of this signature of the response for the model with thinner lithosphere and $\mu_2/\mu_1 = 0.01$ reveals the same sensitivity as previously demonstrated²⁰ for the Maxwell model. For the larger value of $\mu_2/\mu_1 = 0.1$, however, this sensitivity is absent. It is clearly because of this sensitivity to lithospheric thickness variations that the Maxwell and $\mu_2/\mu_1 = 0.01$ models can be made to fit the observed polar wander speed datum with the small viscosity contrast required by sea-level observations.

Figure 4 shows peak present-day predicted free-air gravity anomalies at the centre of the Laurentian and Fennoscandian disk loads as a function of lower-mantle viscosity for the Maxwell model and for the Burgher's bodies with $\mu_2/\mu_1 = 0.1$ and 0.01 which degenerate to it in the limit $\mu_2 \rightarrow 0$. Inspection of these comparisons again shows that the predictions of the Burgher's body with $\mu_2/\mu_1 = 0.01$ are almost identical to those of the Maxwell model for all values of lower-mantle viscosity. For $\mu_2/\mu_1 = 0.1$, however, the present-day free-air gravity

anomalies predicted by the Burgher's body model are considerably enhanced at low values of ν_2 , implying that one effect of transient lower-mantle rheology may be to allow one to fit the observed anomalies with much lower viscosity contrasts than would otherwise be required. In fact if $\mu_2/\mu_1 = 0.1$ were acceptable on other grounds, which we have shown to be unlikely, one could fit the observed anomaly in Fennoscandia without any viscosity contrast at all and the contrast required in Laurentia would be somewhat reduced. The dashed lines on Fig. 4 show the size of the free-air gravity anomaly which would be expected in these two regions if the mantle contained no source of internal buoyancy within its volume. These predictions are shown only for the Burgher's body with $\mu_2/\mu_1 = 0.1$ and demonstrate that even if this value of μ_2/μ_1 were acceptable, the influence of transient rheology would not completely remove the requirement established previously for the Maxwell model that the density discontinuities at 420 km and/or 670 km depth in the mantle be capable of inducing a buoyancy force when they are deflected from their equilibrium positions by the ice sheet loading process. Peltier²¹ and Peltier *et al.*¹⁸ have provided detailed discussions of the importance of this observation from the point of view of several geodynamic processes including that of mantle convection.

Transient rheology and internal buoyancy

The new calculations described above have reinforced the results of recent analyses based on the suggestion of Weertman¹⁰ that the lower-mantle viscosity to which postglacial rebound is sensitive may be a transient rather than a steady-state value. They do also establish, however, that only transient rheologies in which the elastic defect is very large are candidate rheologies which are allowed by the isostatic adjustment data. Since such rheologies operate essentially as Maxwell rheologies with an effective viscosity $\nu_{\text{eff}} = \nu_1 \nu_2 / (\nu_1 + \nu_2)$, it appears that there is very little to be gained in using the more complicated Burgher's body rheology of Peltier *et al.*¹⁵ to describe isostatic adjustment processes. One simply thereby adds additional parameters to the model which are not required by the data. One extremely important implication of the results obtained here is that introduction of transient relaxation into the lower mantle cannot, apparently, completely relieve the requirement that the internal mantle density stratification be able to deliver some buoyant restoring force when it is deformed in the isostatic adjustment process. Without such internal buoyancy in the mantle it is apparently not possible to reconcile observed free-air gravity anomalies with the same viscoelastic model as is required by relative sea-level observations. As discussed in ref. 21, this point is important since it bears on the question of the chemical stratification of the mantle and/or on the extent to which mantle phase transitions behave in a univariant fashion.

In order to make further progress in constraining the extent to which transient relaxation may be required to explain isostatic adjustment observations, we clearly need an independent re-analysis of the conclusions of Richards and Hager¹² concerning the implications of observed isostatic geoid anomalies. If it could be shown that their slab scale anomalies did not in fact require large viscosity stratification, this would demonstrate that no significant transient component of the mantle relaxation spectrum in fact exists. By combining in this way both long-timescale and short-timescale phenomenology which are sensitive to the relaxation process, we shall eventually be able to refine considerably our understanding of the physical mechanisms by which relaxation actually proceeds.

Structure of the protein subunits in the photosynthetic reaction centre of *Rhodopseudomonas viridis* at 3 Å resolution

J. Deisenhofer, O. Epp, K. Miki, R. Huber & H. Michel*

Abteilungen Strukturforschung II and * Membranbiochemie, Max-Planck-Institut für Biochemie, D-8033 Martinsried, FRG

The molecular structure of the photosynthetic reaction centre from Rhodopseudomonas viridis has been elucidated using X-ray crystallographic analysis. The central part of the complex consists of two subunits, L and M, each of which forms five membrane-spanning helices. We present the first description of the high-resolution structure of an integral membrane protein.

The first steps in photosynthesis are mediated by protein-pigment complexes in the photosynthetic membrane. Light energy is absorbed primarily by light-collecting complexes and transferred to reaction centres where it is used with a very high quantum efficiency to transport electrons across the membrane. The reaction centre from the purple bacterium *Rhodopseudomonas viridis* consists of the four protein subunits L, M, H and c-type cytochrome¹ with four covalently linked haem groups². Other prosthetic groups associated with the reaction centre are four bacteriochlorophyll *b* (BChl-*b*), two bacteriopheophytin *b* (BPh-*b*), two quinones, one non-haem ferrous iron and carotenoid(s)¹. Apart from the cytochrome, which has been found as an integral constituent of reaction centre complexes only in some bacteria, it is generally accepted that reaction centres of purple bacteria are organized in a very similar way. This can be concluded from the subunit composition, from homology between the amino-acid sequences of the L and M subunits, from chromophore composition and from similar spectroscopic and electron-transfer properties (for reviews see, for example, refs 3–7).

The reaction centre from *Rps. viridis* was the first to be crystallized⁸; the photochemical activity of the crystalline material has been demonstrated⁹. An X-ray structure analysis of these well-ordered crystals allowed the calculation of an electron-density map at 3 Å resolution—an atomic model of the prosthetic groups was deduced from this map¹⁰. The arrangement of the pyrrole ring systems of BChl-*b* and BPh-*b* molecules in the central region of the reaction centre (assumed to consist of the subunits L and M) shows an approximate 2-fold symmetry with two closely associated BChl-*b*s near the symmetry axis. These two molecules form the 'special pair' postulated from the results of spectroscopic investigations¹¹. The special pair is symmetrically in contact with two BChl-*b* molecules, each of which has a BPh-*b* as a neighbour. These chromophores form two branches that are apparently suitable as electron pathways. The right-hand side branch (see Fig. 4 in ref. 10) ends with a quinone close to the non-haem iron located on the local symmetry axis. The second quinone and the carotenoid are either not present or disordered in the crystal. The four haem of the cytochrome show a roughly linear arrangement with one haem near the special pair¹⁰.

This chromophore model correlates well with the electron-transfer steps determined from spectroscopy¹². After absorption of light an electron is transferred from the excited primary electron donor (the special pair), possibly via a BChl-*b*¹³ to an intermediate acceptor (BPh-*b*), and further to a primary quinone acceptor (Q_A or tightly bound quinone). Q_A reduces a secondary quinone acceptor (Q_B or loosely bound quinone). Q_B, when fully reduced and protonated, is commonly assumed to leave the reaction centre, and to be replaced from a quinone pool in the membrane¹⁴. The oxidized special pair is reduced by the cytochrome.

Here we report further interpretation of the electron-density map. We describe the folding of the polypeptide chains of the protein subunits in the reaction centre and the spatial relation between protein and prosthetic groups. With this structure we can present the first model of an integral membrane protein determined at nearly atomic resolution.

Electron-density map

The reaction centre crystals belong to the space group P4₃2₁2 with unit cell constants of $a = b = 223.5 \text{ Å}$, $c = 113.6 \text{ Å}$, and contain one centre per asymmetrical unit^{8,10}. The electron-density map at 3 Å resolution was calculated with phases from multiple isomorphous replacement using five heavy-atom derivatives; this map was improved further by solvent flattening¹⁵. A detailed report on data collection, map calculation and arrangement of prosthetic groups is described elsewhere¹⁰.

The chromophore model facilitated the identification of the protein subunits of the reaction centre. The haem groups are evidently bound to the cytochrome subunit; BChl-*b*, BPh-*b*, non-haem iron and quinone are known to be associated with the subunits L and M in reaction centres from purple bacteria^{4,16,17}. Available amino-acid sequences of 46, 30 and 28 residues¹⁸ at the amino-termini of the subunits L, M and cytochrome, respectively, could be located in the map. The H subunit was identified on the basis of a partial gene sequence corresponding to 68 residues from the amino terminus.

For model building of the protein subunits a minimap (scale 2 mm Å⁻¹), and interactive display systems (Vector General 3400 and Evans & Sutherland PS330) driven by the program FRODO¹⁹ were used. Optimum fit of helices and large side chains to the density was achieved with the real-space refinement option in FRODO²⁰. Segments with unknown amino-acid sequence were built as polyalanine. Residue numbers were prefixed with the letters L, M, C and H, respectively, for distinction between subunits.

The good quality of the map allowed unambiguous chain tracing even in the absence of amino-acid sequence information. Recently the complete amino-acid sequences of the subunits H²¹, L and M (H.M., K. A. Weyer, H. Gruenberg, I. Dunger, D. Oesterhelt and F. Lottspeich, in preparation) became available from the corresponding gene sequences and were incorporated into the model. The amino-acid sequence of the cytochrome, presently being investigated with protein-chemical methods (K. A. Weyer, H.M. and F. Lottspeich, unpublished data), is still incomplete. However, peptide sequences resulting from this work could be located in the electron density and used for model building. Currently, these pieces add up to ~60% of the residues. The absence of a contiguous sequence for the cytochrome leads to an uncertainty in the residue numbering for this subunit caused by possible erroneous omission or insertion of residues during chain tracing.

Fig. 1 (Parts *a*, *b* above.) Stereo drawing of the complete reaction centre complex in two orientations. Panel *a* is rotated with respect to *b* by 90° around a vertical axis. Green, cytochrome; orange, L; blue, M; purple, H; yellow, prosthetic groups. Figs 1-5 were produced by a computer program written by A. M. Lesk and K. D. Hardman³⁰.

Fig. 3 (Left) Stereo drawing of the L-M complex and associated chromophores viewed along the L-M local diad. Protein chains are represented as ribbons. Colours as in Fig. 1.

Fig. 2 Stereo drawings of *a*, subunit L; *b*, subunit M represented as ribbons in identical orientations. Transmembrane helices A-E are labelled.

A crystallographic *R*-value ($R = \sum ||F_{\text{obs}}| - |F_{\text{calc}}|| / \sum |F_{\text{obs}}|$) was calculated when the model contained ~70% of the correct sequence. For 46,658 reflections between 7- and 3-Å resolution we obtained $R = 0.359$; this value is exceptionally low for a protein model before crystallographic refinement.

The reaction centre complex

The course of the polypeptide chains and the location of the prosthetic groups of the centre are shown in Fig. 1. The central part consists of the subunits L and M which bind the BChl-*b*, BPh-*b*, the quinone and the non-haem iron. The cytochrome subunit is bound to a flat surface of L-M close to the special pair of BChl-*b*. A large contact area and the carboxy-terminal arm of the M subunit are responsible for the tight binding of the cytochrome to L-M. The major part of the H subunit is in contact with the other flat surface of the L-M complex that is close to the binding sites of the quinone and the non-haem iron. The amino-terminal segment of H forms a helix extending from the cytochrome side along the surface of the M subunit. The longest dimension of the reaction centre complex is ~130 Å between the tips of cytochrome and H subunit.

In our electron-density map there is no clear indication of the presence of ordered lipid or detergent that would provide direct evidence on the position and orientation of the membrane relative to the reaction centre complex. However, the highly hydrophobic surface of the central region of the centre indicates that this part (that is, the subunits L and M and the amino-

terminal helix of H) spans the membrane. The same conclusion follows from the fact that with electron transfer from the special pair to the quinone(s) a charge separation across the membrane takes place. Recently, the amino-terminus of the L-subunit was localized at the cytoplasmic side of the photosynthetic membrane from *Rhodospirillum rubrum*²². Assuming the same orientation for the reaction centre from *Rps. viridis*, this means that the cytochrome is located at the periplasmic side, and the major part of the H subunit is at the cytoplasmic side of the membrane.

Subunits L and M

Subunit structure. Although L and M differ in length by 50 residues (L, 273 residues; M, 323 residues), their folding is generally very similar. Using the method of Rossmann and Argos²³, 219 C α -positions of M could be rotated onto corresponding positions of L to an r.m.s. distance of 1.25 Å. The rotation axis is defined by the polar angles $\phi = 43^\circ$, $\Psi = 39.4^\circ$, $\kappa = -179.3^\circ$ (where ϕ is the angle between the rotation axis and *y*-axis; ψ is the angle between projection of the rotation axis on *x-z* plane and *x*-axis; and κ is the rotation angle). At the present level of accuracy this L-M local diad is virtually identical to the local diad relating ring atoms of BChl-*b* and BPh-*b* ($\phi = 43^\circ$, $\psi = 37.6^\circ$, $\kappa = -177.1^\circ$)¹⁰. Figure 2 shows ribbon drawings of subunits L and M in the same orientation. Outstanding structural features of both subunits are five long helical regions (mostly α -helix) numbered A-E (LA-LE in the L subunit,

Fig. 4 Stereo drawing of subunit H (ribbon representation).

MA-ME in the M subunit). They consist mainly of hydrophobic residues, many of which are exposed to the environment. Therefore, we assume that these helices span the membrane; their lengths range between 24 and 30 residues (A, L32-L55, M52-M78; B, L84-L112, M110-M139; C, L115-L140, M142-M167; D, L170-L199, M197-M225; E, L225-L251, M259-M285). The helices are arranged side by side in a concave layer in the order A, B, C, E and D, so that helices C and E are neighbours and run approximately parallel, whereas all other neighbouring helix pairs within a subunit run roughly antiparallel. The angles between the helix axes and the L-M local diad are $<25^\circ$ for the helices A, B, C and E and $\sim 38^\circ$ for helix D.

On both sides of the helical region the remaining segments of L and M form two flat surfaces in intimate contact with the subunits cytochrome and H, respectively. The surface in contact with the H subunit consists of the amino-terminal segments and the helix connections D-E; helix connections B-C are short turns which also come close to this surface. Helix connections A-B and C-D and carboxy-terminal chain segments contribute to the cytochrome contact surface. Apart from as the transmembrane helices, further segments with helical conformation are located in both contact surfaces: L208-L220, M36-M42, M240-M255 at the H contact surface and L149-L164, L259-L269, M80-M88, M178-M192 and M281-M300 at the cytochrome contact surface. Only at the amino termini of L and M two-stranded antiparallel β -sheets are found comprising segments L24-L26, L29-L31 and M27-M35, M44-M51, respectively.

Major structural differences between L and M are observed at or near the contact surfaces. From the amino terminus to the start of transmembrane helix A, M is 20 residues longer than L; these additional residues mainly contribute to the two-stranded antiparallel β -sheet at the H contact surface. The helix connection D-E of M, which is also at the H contact surface, is seven residues longer than in L. At the cytochrome contact surface the helix connection A-B is seven residues longer in M than in L. From the end of helix E to the carboxy terminus M is 16 residues longer than L; the additional residues of M form the arm that folds along the surface of the cytochrome, and appears to contribute to the tight binding of this subunit in the reaction centre complex.

L-M association. The subunits L and M cohere predominantly at or near the H contact surface. Helices D, E and the C-D connection of one subunit intercalate between helices C and E

in the other subunit (see Fig. 3). Helices LD, LE, MD and ME come close to the L-M local diad, and are in contact with each other (see Fig. 1). The non-haem iron is bound between these four helices, each of which contributes one ligand to the iron. Further L-M contacts at the H contact surface are contributed by the helix connections D-E and by the amino-terminal segments (Fig. 3).

Near the cytochrome contact surface a gap opens up between helix pairs LD, LE and MD, ME to accommodate the special pair on the L-M local diad. Helices C and E are bent away from the L-M local diad near the cytochrome contact surface, and so increase the space available for the accessory BChl-*b* and the BPh-*b* molecules. Both L and M contribute one half of the cytochrome contact surface with apparently weak lateral contacts between these halves. At the intersection of the L-M local diad and the cytochrome contact surface the side chain of residue Tyr L162 is located between the closest haem group and the special pair; it may be involved in electron transfer.

With its two only partially overlapping layers of transmembrane helices the L-M complex has a remarkably non-globular structure in which the surface area accessible from the environment appears to be significantly larger than in globular water soluble proteins. Its shape suggests that the contact surfaces are parallel and that the L-M local diad is perpendicular to the membrane plane, in agreement with chromophore orientations determined optically in oriented *Rps. viridis* cells^{24,25}.

Binding of prosthetic groups in L-M. As reported previously¹⁰, protein side chains are bound to the Mg^{2+} ions of BChl-*b*; all four BChl-*b* ligands are histidines as most BChl-*a* ligands found in the BChl-*a* protein from *Prosthecochloris aestuarii*^{26,27}. The BChl-*b*s are designated BC_{LP} , BC_{MP} , BC_{LA} and BC_{MA} , where L and M refer to the ligation and P and A indicate 'special pair' and 'accessory', respectively. The Mg^{2+} ligands of BC_{LP} and BC_{MP} are near the start of the transmembrane helices LD (L173), and MD (M200), respectively. The Mg^{2+} ligands for BC_{LA} and BC_{MA} are in the helix connections C-D (L153 and M180, respectively). The BPh-*b*s are named BP_L and BP_M according to predominant interactions with subunit L or M. Each BPh-*b* binding site is a pocket formed mainly by non-polar residues from both subunits; there are no polar interactions between the protein and the tetrapyrrole nitrogens. BP_L (BP_M) is located near the centres of helices LC, LE (MC, ME) with its ring plane parallel to the axis of helix MD (LD). Accessory BChl-*b* and BPh-*b* are partially accessible from the environment.

Fig. 5 Stereo drawing of the cytochrome subunit. The protein chain is represented as a ribbon; haem groups and linked cysteine side chains are shown as line drawings.

The non-haem iron is bound by five protein ligands, four histidines and one glutamic acid. The histidines are located in the transmembrane helices LD (L190), LE (L230), MD (M217) and ME (M264), and obey the L-M local 2-fold symmetry. They are arranged approximately in a plane perpendicular to the L-M local diad. The fifth iron ligand, Glu M232, sits on the local L-M diad. The structure near the non-haem iron is in good agreement with conclusions drawn from extended X-ray absorption fine-structure studies^{28,29}.

As reported previously¹⁰, we believe that the quinone identified in the electron-density map is the tightly bound quinone Q_A (menaquinone-9 in *Rps. viridis*³⁰). Q_A is located near BP_L ; its head group is bound exclusively to residues of M in the helix connection D-E with close contacts to His M217 (one of the iron ligands), to the peptide nitrogen of M258 and to Trp M250 whose side chain is nearly parallel to the Q_A head group. Its isoprenoid chain is mainly in contact with BP_L and with residues of L. It was shown that the loosely bound Q_B (ubiquinone-9 in *Rps. viridis*³⁰) can be lost during purification of the reaction centres¹⁴ or during crystallization³⁰. To find the Q_B site, the binding of the competitive inhibitors for Q_B *o*-phenanthroline³¹, terbutryn (a herbicide)³² and of ubiquinone-1 in the crystal was studied by soaking these compounds into the crystals (*o*-phenanthroline, 2 mM for 3 days; terbutryn, 1 mM for 3 days, followed by 0.01 mM for 3 days; ubiquinone-1, 1 mM for 3 days), collecting X-ray data and analysing these data using the difference-Fourier technique. These studies showed binding of the three compounds to a pocket formed near the H contact surface by parts of the transmembrane helices LD and LE, and by the LD-LE connecting segment. Additional binding sites were observed for *o*-phenanthroline (two), and ubiquinone-1 (seven). From these results we conclude that the single common binding site of the three compounds is the Q_B binding site. Only this site, which is related to the Q_A site by the L-M local diad, is close to the non-haem iron as required to explain the broadening of electron-spin resonance lines observed for Q_B^- (ref. 33). The Q_B site is in contact to the iron ligand His L190; the iron itself is located midway between Q_A and Q_B . This arrangement strongly suggests that the iron participates in electron transfer from Q_A to Q_B . However, experiments with iron-depleted reaction centres from *Rps. sphaeroides* showed that electron transfer is only moderately slower in the absence of the iron³⁴.

The binding sites of Q_A and Q_B are in regions of L and M, where both subunits markedly deviate from the L-M local symmetry. Whereas Q_A is completely shielded from the H subunit by the M chain, the probable Q_B binding site is accessible from H through an opening in the H contact surface. These observations correlate the different binding of Q_A and Q_B to structural differences between L and M; they also suggest that one function of H is related to Q_B binding. A more detailed description of the reaction centre structure near the prosthetic groups will be given elsewhere.

The H subunit

With 258 residues H is the smallest subunit of the reaction centre. The course of its polypeptide chain is shown in Fig. 4. The amino-terminus is near the cytochrome contact surface of L-M; residues H1, H2, H3 and H5 are in contact with residues from the cytochrome. Residues H12 to H37 form a helix which runs along the convex side of the surface formed by the transmembrane helices of M, with contacts to helices ME and MD (see Fig. 1). The amino-acid sequence in this helical region up to residue H32 is also primarily hydrophobic; the carboxy-end of the helix (H33-H37) and further on to H39 consists of charged residues (Arg-Arg-Glu-Asp-Arg-Arg-Glu) which interact partly among themselves, and probably also with the polar head groups of membrane lipids *in vivo*.

Altogether we find 11 transmembrane helices in the reaction centre complex, 6 running from the cytoplasmic side to the periplasmic side and 5 running in the opposite direction. The question of whether the dipole moments of these helices can facilitate electron transfer across the membrane, as proposed recently³⁵, requires a detailed inspection of the model and will be discussed elsewhere.

The absence of significant electron density for residues H48 to H56 near the end of the transmembrane helix indicates that this segment is disordered in the crystal. The segment H57-H115 lies on the surface of L-M; residues H66-H70 and H74-H78 form a two-stranded antiparallel β -sheet. The remainder of H is folded into a globular domain. Residues H156-H120 form two layers of β -sheet which enclose a hydrophobic core. Both sheets consist of three strands and show a right-handed twist. In sheet 1 the strands (H162-H174, H179-H187 and H191-H197) are antiparallel; in sheet 2 the middle strand (H207-H210)

is accompanied by an antiparallel strand (H200–H204) and a parallel strand (H156–H159). Near the carboxy-terminus residues H231–H249 form a helix that runs parallel to the H contact surface of L–M.

Little is known about the function of H in the reaction centre complex. Crosslinking studies¹⁶ indicate that H is close to the light-collecting complexes in the membrane; this observation suggests that H has a role in determining the relative orientation of light-collecting complexes and reaction centre. As mentioned above, H may also play a role in Q_B binding—residue H177 (Glu) and its neighbours have access to the Q_B binding pocket in subunit L. They could be involved in donating protons to the photochemically reduced Q_B . This is in accord with experimental results on L–M complexes of *Rps. sphaeroides*³⁶ which show abnormal electron transfer from Q_A to Q_B in the absence of H.

The cytochrome

The present model of the cytochrome subunit contains 333 residues. Figure 5 shows the course of the polypeptide chain and the location of the haem groups. Near the amino-terminus, residues C7–C11 and C20–C23 form an antiparallel β -sheet that lies on the L half of the cytochrome contact surface. From there the chain proceeds to the tip of the subunit (around C50); residues C25–C37 form a helix. In the following bulk of the subunit four recurring structural motifs can be observed: a helix runs parallel to the ring plane of each haem group (residues C67–C82, C102–C119, C222–C240 and C262–C286, respectively); the haems are covalently attached near the carboxy termini of these helices where the chains turn back towards the haems. The electron density strongly indicates that these covalent links are thioether bridges, and that the sequences of the haem binding segments are Cys–X–X–Cys–His as in other *c*-type cytochromes; the His residues are the fifth ligands to the haem irons. The haems are numbered according to the order of attachment to the protein; for haem 1 the first covalent link is to residue C87, haem 2, C132, haem 3, C244 and haem 4, C305. All haem irons appear to be six-coordinated; the sixth ligands to the irons of haem 1, 2 and 3 are located in the helices associated with the haems (residues C74, C110 and C233, respectively). The sixth ligand to the haem 4 iron (C124) is in the segment between the helix parallel to haem 2 and the haem 2 attachment site. According to the electron density the sixth ligands to the haem irons could be histidines or methionines.

As reported previously¹⁰, the haem groups are arranged with an approximate 2-fold symmetry: pyrrole ring atoms of haems 3 and 4 can be rotated onto those of haems 1 and 2 with polar angles $\phi = 117.2^\circ$, $\psi = -70.2^\circ$ and $\kappa = -176.5^\circ$ to an r.m.s. distance of 0.41 Å. Haems 1 and 2 and haems 3 and 4 are related by improper rotations ($\sim 105^\circ$) with large screw components (~ 12 Å). Using the same method as for the L–M comparison²³, 66 C α positions from the region C226–C315 could be rotated onto corresponding C α positions from between C67 and C142 to an r.m.s. distance of 1.1 Å. The polar angles of this rotation are $\phi = 116.7^\circ$, $\psi = -68.9^\circ$ and $\kappa = -177.8^\circ$, very close to those for the haem rotation. This internal 2-fold symmetry includes about one third of the cytochrome subunit. More extended structural homologies with 2-fold symmetry in protein molecules have been reported for rhodanese³⁷ and γ -crystallin³⁸. The intramolecular symmetry is broken in the segment connecting the binding sites of haem 2 and 3; this segment contributes to the contact of cytochrome to L–M. The carboxy-terminal segment ends near the helix associated with haem 2. Haem 1 is accessible from the environment at its pyrrole rings I and IV; haem 2 appears to be almost completely buried; and haems 3 and 4 are accessible at their propionic acid groups. Pyrrole rings I and IV of haem 3 are closest to the special pair of BChl-*b* in the L–M complex. Apparently, protein folding in the cytochrome subunit of the reaction centre is different from both cytochromes C2 and cytochromes C3 with known three-dimensional structure (see ref. 39 for review).

Structure of related proteins

Reaction centres from other purple bacteria. Amino-acid sequences are known for the reaction centre subunits L, M and H from *Rps. capsulata*⁴⁰, and for L and M from *Rps. sphaeroides*^{41,42}. The sequences of L and M from *Rps. viridis* show between 50 and 60% homology with those of the corresponding subunits from the other two bacteria. On the basis of hydrophobicity five transmembrane helices each were postulated^{40–42} in segments of L and M homologous with the transmembrane helix regions in our model. All the ligands to the BChl and to the non-haem iron described above are also conserved, and the polypeptide segments connecting these ligands have the same length in all three organisms. These observations clearly indicate that the structures of L and M from *Rps. capsulata* and *Rps. sphaeroides*, and the arrangement of BChls and non-haem iron are very similar to those found for *Rps. viridis*. Significant differences in polypeptide chain length occur exclusively at the carboxy-termini where L from *Rps. viridis* is shorter by 8 residues, and M is longer by 17 residues. These additional residues of M are in contact with the cytochrome in *Rps. viridis*: the reaction centres of *Rps. capsulata* and *Rps. sphaeroides* lack a permanently bound cytochrome subunit.

For the H-subunits from *Rps. capsulata* and *Rps. viridis* the sequence homology is 37% (ref. 21). Common features of these two H-subunits include a hydrophobic region near the amino terminus which corresponds to the transmembrane helix of H in our model. In addition, many of the residues involved in the contact between H and L–M are conserved in both organisms, so that structural similarity can also be expected between the H subunits from *Rps. capsulata* and *Rps. viridis*.

Photosystem II. Recently, amino-acid sequences of polypeptides from photosystem II reaction centres^{43–47} have been reported. Sequence homologies were found between L and M of purple bacteria and the D1 polypeptide (also referred to as Q_B protein or herbicide binding polypeptide) from photosystem II of higher plants^{40,42} and between D1 and D2 (ref. 45) which is also a constituent of photosystem II. In these plant proteins, histidines which correspond to the ligands of the special pair, and to those of the non-haem iron in our model are conserved. Even a Trp residue corresponding to M250, which forms part of the Q_A binding site in reaction centres of purple bacteria, can be found in the D2 proteins. These observations corroborate our recent proposal⁴⁸ that proteins D1 and D2 form the core of the photosystem II reaction centre, similar to the subunits L and M in purple bacteria. Based on functional and sequence homology we believe that D1 and D2 span the membrane five times, contrary to a proposed seven-helix structure⁴⁹, where the helix connections A–B and D–E were probably misinterpreted as transmembrane helices.

We thank Professor D. Oesterhelt for support and the Deutsche Forschungsgemeinschaft (SFB 143) for financial help.

Identification of the signal molecules produced by wounded plant cells that activate T-DNA transfer in *Agrobacterium tumefaciens*

Scott E. Stachel, Eric Messens*, Marc Van Montagu & Patricia Zambryski

Laboratorium voor Genetica and * Histologisch Instituut, Rijksuniversiteit Gent, B-9000 Gent, Belgium

We show here that Agrobacterium tumefaciens virulence (Vir) gene expression is activated specifically by the plant molecules acetosyringone (AS) and α -hydroxyacetosyringone (OH-AS). These molecules induce the entire vir regulon in Agrobacterium as well as the formation of T-DNA intermediate molecules. AS and OH-AS occur specifically in exudates of wounded and metabolically active plant cells and probably allow Agrobacterium to recognize susceptible cells in nature.

SOIL bacteria often form specialized interactions with plant cells. Usually a particular bacterium interacts with only a few species and/or types of plant cells^{1,2}. A primary step in the formation of a bacterial/plant interaction is the detection by the bacterium of the appropriate susceptible plant cell. This recognition then triggers the activation of the bacterial genes whose products direct the development and/or maintenance of the interaction. The soil is a complex biological and chemical environment, and the signals that mediate the detection of a specific plant cell by a bacterium are unknown.

A. tumefaciens, a soil phytopathogen, genetically transforms dicotyledonous plant cells to cause the neoplastic disease crown gall^{3,4}. Only cells that have been wounded are seen to be susceptible^{5,6}. The bacterium transfers a specific segment of DNA, the T-DNA, from its large (> 200 kilobases, kb) tumour-inducing (Ti) plasmid to the susceptible plant cell, where it becomes integrated into the nuclear genome^{7,8}. In the Ti plasmid, the T-DNA is defined and bounded by identical 25-base pair (bp) direct repeats; only DNA between these T-DNA borders is transferred to the plant genome⁹⁻¹². During co-cultivation with plant cells, independent T-DNA circles are formed in *Agrobacterium*; these molecules arise by a specific recombination between the 25-bp sequences at the ends of the T-DNA and are potential intermediates in the transfer of the T-DNA from *Agrobacterium* to the plant cell¹³.

The Ti plasmid genes required for plant transformation are not contained in the T-DNA but are located in the ~40-kb *vir* region¹⁴⁻¹⁶. Genetic analysis of the *vir* region of the A6 Ti plasmid has shown that it encodes at least six separate complementation groups, *virA*, *B*, *C*, *D*, *E* and *G*, and *pinF* that are organized as a single regulon (ref. 17; S.E.S., in preparation). In the vegetative bacterium only *virA* and *virG*, the *vir* regulatory genes, are significantly expressed; however, when *Agrobacterium* is co-cultivated with plant cells the expression of *virB*, *C*, *D*, *E*,

G and *pinF* is induced to high levels^{17,18}. This activation of *vir* expression by plant cells probably initiates the steps of T-DNA transfer and integration into the plant cell genome. We have shown that *vir* induction and the production of T-DNA circles is mediated by a small diffusible factor produced by actively growing plant cells¹⁷. Here, we purify and establish the chemical identity of this factor, and demonstrate that its production is related to plant cell wounding and that its recognition by the bacterium is a highly specific process. This factor is likely to be the signal that allows *Agrobacterium* to recognize in nature a plant cell susceptible to transformation.

Purification of signal molecules

To purify the plant molecule(s) that specifically signals *Agrobacterium* to initiate its interaction with plant cells requires first, an efficient and quantitative bioassay for a primary event in this transformation process, specifically the induction of *vir* gene expression; and second, a starting source of the signal molecule(s). We have previously described an assay for *vir* induction in *Agrobacterium* that used gene fusions between the pTiA6 *vir* loci and the *Escherichia coli lacZ* gene^{17,18}. Briefly, in a bacterium carrying a *vir::lac* gene fusion, the production of β -galactosidase (the *lacZ* gene product) is controlled by the *vir* locus to which *lacZ* has been fused. Thus, the state of expression of the locus can be monitored by measuring the β -galactosidase activity present in the bacterium; increased activity indicates increased *vir* expression. (The relative amount of induced activity reflects the relative amount of *vir*-inducing activity to which the cell has been exposed.) Here we use *Agrobacterium* strain A348(pSM30) (ref. 17) to detect and measure *vir*-inducing activity. This strain contains wild-type pTiA6 and pSM30, a *virB::lac* fusion plasmid, and gives high levels (up to ~100-fold of basal activity) of induced β -galactosidase activity¹⁷.

Fig. 1 RPC/FPLC fractionation of the *vir*-inducing activity in plant-cell exudates. The organic compounds present in plant cell medium conditioned with root culture (*cmr*; A, B), or with leaf disks (*cml*; C), were prepared by chloroform extraction and analysed by RPC/FPLC. The material analysed in A, B and C was prepared from 2 litres *cmr*, 40 ml *cmr* and 50 ml *cml*, respectively. Each sample was fractionated on a C-2/C-18 RPC column eluted with a linear methanol gradient. In A and C, column fractions were bioassayed for *vir*-inducing activity in *Agrobacterium*. The diagonal line represents the elution gradient and the solid line indicates the ultraviolet absorbance measured at 280 nm of the column fractions; shaded curves indicate relative specific units of β -galactosidase activity induced in the *virB::lacZ* tester strain A348(pM30) by the column fractions. The major peaks of *vir*-inducing activity in A are indicated by arrows labelled A, B, C and D. B, Arrows indicate peaks corresponding to peaks A, B and D of A.

Methods. Root culture of *N. tabacum* transformed with *Agrobacterium rhizogenes* A15834 was grown and maintained as described previously¹⁷. Transformed roots were used because they are easy to propagate. Every 72 h the conditioned medium (*cmr*) was removed and stored at -20°C . Leaf disks were prepared from 6-week-old untransformed *N. tabacum* SR1 plants, and 2-g samples of 1.5-cm-diameter disks were incubated in 50 ml MS medium (Murashige and Skoog²⁸ salts, 3% sucrose, supplemented with 0.018% K_2HPO_4 , 0.01% inositol, 0.0001% biotin, pH 5.5) in 150-mm Petri dishes. After 72 h, the conditioned medium (*cml*) was removed and stored at -20°C . The conditioned medium (*cmr* and *cml*) was filtered through 0.22 μm nitrocellulose and the filtrate extracted twice with a 25% volume of chloroform and the pooled chloroform phase was back-extracted with 1 vol. MS medium, rotary-evaporated to dryness and resuspended in 500 μl 20% CH_3OH , 0.1% CH_3COOH for analysis by RPC/FPLC. (Note that initial solvent extraction experiments were performed to determine the solvent partitioning character of the *cmr* and *cml* *vir*-inducing activities. In these experiments 50 ml of the respective conditioned medium was extracted with chloroform; the interphase and chloroform phase were lyophilized and each resuspended in 2 ml MSSP (MS medium supplemented with 12.5 mM sodium phosphate, pH 5.5¹⁷), and the aqueous phase was blown with a stream of air to remove traces of chloroform. Each of these samples was bioassayed for *vir*-inducing activity; only the chloroform phase material contained this activity.) A Pep RPC pre-packed 5 mm \times 50 mm column (HR5/5) containing 6- μm silica particles with C-2 and C-18 alkyl side chains (Pharmacia) was pre-equilibrated with 10% CH_3OH , 0.1% CH_3COOH . The column was run at a flow rate of 0.7 ml min^{-1} using a Pharmacia FPLC system equipped with the LCC500 chromatographic programmer. A single-path ultraviolet monitor was used to monitor absorbance at 280 nm. The column was eluted with a linear gradient of 10–60% $\text{CH}_3\text{OH}:\text{H}_2\text{O}$ (v/v), 0.1% CH_3COOH . We collected 40 1.4-ml (2-min) fractions; 140- μl aliquots (A) or the entire fractions (C) were lyophilized, resuspended in 1.5 ml MSSP and bioassayed for *vir*-inducing activity. Overnight cultures of strain A348(pSM30) were centrifuged and resuspended in MSSP medium. Material to be tested for *vir*-inducing activity was inoculated with bacteria at 0.1 absorbance unit ml^{-1} at 600 nm cm^{-1} . Incubations were for 10 h at 28°C and 200 r.p.m. Specific units of β -galactosidase activity were determined as described previously^{17,18} and are expressed as U per bacterial cell.

Induction of *vir* expression occurs during co-cultivation of *Agrobacterium* with plant cells, and during incubation of bacteria in plant-cell exudates. We have shown that the medium in which *Nicotiana tabacum* root culture has grown (designated *cmr* for conditioned medium roots) contains substantial amounts of a *vir*-inducing activity¹⁷. This activity stimulates the expression of each of the inducible pTiA6 *vir* loci, and also the formation of T-DNA circular intermediates, indicating that it triggers in *Agrobacterium* the initiation of plant cell transformation. This activity has relative molecular mass less than 1,000; is stable to boiling, freezing, lyophilization, and high and low pH; and is partially hydrophobic, as it is retained by silica C-18 and completely elutes from this matrix with 40% CH_3OH (ref. 17). Here we purify and identify this *cmr* activity.

The above properties suggest that the *cmr* *vir*-inducing activity is composed of one or more small organic molecules; that it completely partitions into the organic solvent chloroform (Fig. 1) confirms this identity, and provided a basis for its purification. The *cmr* *vir*-inducing activity was fractionated by reverse-phase chromatography (RPC) using a high-resolution fast-performance liquid chromatography (FPLC) system. Activity was localized to two major and two minor peaks that had eluted, respectively, with 18 (peak A), 27.5 (peak B), 32

(peak C) and 42% (peak D) CH_3OH (Fig. 1A). Thus, the *cmr* *vir*-inducing activity is represented by at least four distinct compounds. When less material is loaded onto the FPLC column (Fig. 1B), peak B is the major component of the organic fraction of *cmr*. Because of their low abundance, the peak C and peak D activities were not analysed further. The signal molecules in peaks A and B were purified to homogeneity by further RPC fractionation and analysed by gas chromatography/mass spectroscopy (GC-MS) (Fig. 2) and ultraviolet absorption spectroscopy (Fig. 3).

Identification of *vir* inducers

The peak B compound, the major *cmr* *vir*-inducing molecule, is 4-acetyl-2,6-dimethoxyphenol, based on several experimental observations: (1) The GC/MS spectrum of the peak B compound

Fig. 2 Mass spectra of *vir*-inducing molecules. The mass spectra of purified peak B compound (Fig. 1), purified peak A compound (Fig. 1) and authentic acetosyringone (Janssen Chimica), are shown in *a*, *b* and *c*, respectively. Vertical axes, relative intensity of the fragment ions; horizontal axes, the mass/charge ratio of the fragment ions. The determined chemical formulae and structures of peak B and peak A (from Fig. 1) are indicated in *a* and *b*, respectively.

Methods. The biologically active compounds present in the peak A and B fractions were purified to homogeneity by RPC/FPLC; fractionation conditions were identical to those described in Fig. 1, except for the column solvent. The fractions containing peak A or peak B (from Fig. 1A) were pooled, lyophilized, resuspended in 5% acetonitrile, 0.1% trifluoroacetic acid (TFA) and injected onto the C-2/C-18 column equilibrated with this buffer. The column was eluted with a linear gradient of 5–30% acetonitrile, 0.1% TFA, and monitored for ultraviolet absorbance at 280 nm and for biological activity. For each sample a single peak was resolved from other minor ultraviolet-absorbing compounds, and a portion of the peak fraction was lyophilized, dissolved in 500 μ l chloroform and evaporated to 40 μ l under a nitrogen stream for GC/MS analysis. Separate portions of each sample were dissolved in CH_3OH for ultraviolet absorption analysis (Fig. 3) and in MSSP for analysis of biological activity. We injected 0.5 μ l of sample into a 0.32 mm \times 25 m Carlo Erba (HRGC) gas chromatography column SF-52, directly coupled to a Finnigan 4000 mass spectrometer. GC fractionation was with a 50–250 $^\circ$ gradient, 5 $^\circ$ min $^{-1}$. Data were collected and processed on a Nova 3 computer (Data General).

(Fig. 2a) indicates a molecule of relative molecular mass (M_r) 196, chemical composition $\text{C}_{10}\text{H}_{12}\text{O}_4$ and general structure acetyl-dimethoxyphenol. (2) Comparison of the ultraviolet absorption spectrum of the peak B compound in CH_3OH with its spectrum in $\text{CH}_3\text{OH}/\text{NaOH}$ (Fig. 3a) indicates that the molecule exhibits a strong absorption shift to longer wavelengths in the presence of NaOH; this base-induced redshift is diagnostic of phenolic compounds in which the phenolic hydroxyl group is *para* (but not *ortho* or *meta*) to a conjugated ring substituent, such as a ketone or allyl group¹⁹. (3) The *p*-hydroxyl derivative, 4-acetyl-2,6-dimethoxyphenol, commonly termed acetosyringone (AS), is commercially available and greatly stimulates *vir*

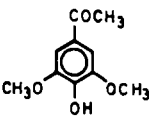

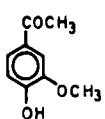

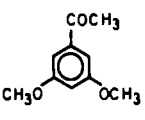

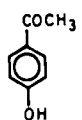

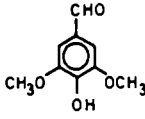

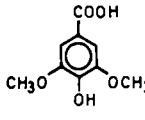

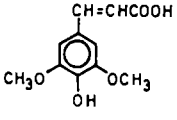

Fig. 3 Ultraviolet absorption spectroscopy of *vir*-inducing compounds purified from *cmr*. Spectra were determined in both CH_3OH (solid line) and $\text{CH}_3\text{OH}/\text{NaOH}$ (dashed line). *a*, Spectra of peak B compound; *b*, spectra of commercially obtained acetosyringone; *c*, spectra of peak A compound.

Methods. Absorption spectra were measured in a Beckman DU-6 spectrophotometer scanning at 60 nm min $^{-1}$. For each compound dried material was resuspended in CH_3OH (HPLC grade, Rathburn Chemicals) to an approximate concentration of 50 μM , and scanned against CH_3OH as a blank solution. The pH of the sample was subsequently adjusted to basic pH by the addition of 1 M NaOH to 20 mM and the sample scanned against $\text{CH}_3\text{OH}/20 \text{ mM NaOH}$. (Note that when the base-adjusted sample of each compound is readjusted to acid pH by adding 1 M HCl to 40 mM, the determined spectrum is equivalent to the original CH_3OH spectrum of the compound (data not shown). Thus, the base-induced redshift of each compound is fully reversible in the conditions used.)

expression in *Agrobacterium* (see below). AS and the purified peak B compound co-elute on RPC/FPLC (data not shown) and their GC/MS spectra are indistinguishable (Fig. 2). Furthermore, their respective ultraviolet spectra, both in CH_3OH and in $\text{CH}_3\text{OH}/\text{NaOH}$, are identical (Fig. 3a, b). (4) The quantitative *vir*-inducing activities of authentic AS and the peak B compound are equivalent. In the experiment described in Fig. 4, the units of induced β -galactosidase activity as a function of concentration of inducing compound were determined for each compound at several concentrations; the respective activity/concentration curves are identical.

The peak A compound, the second major *cmr vir*-inducer, is 4-(2-hydroxyacetyl)-2,6-dimethoxyphenol, termed α -hydroxy acetosyringone (OH-AS), an analogue of AS. This identification is based on the following observations: (1) The GC/MS spectrum of the peak A compound (Fig. 2c) indicates a molecule of M_r 212 whose only significant fragmentation product has M_r 181. The GC/MS spectrum of compound A following trimethylsilylation indicates a mass increase corresponding to two trimethylsilyl groups (data not shown). Thus, compound A contains two hydroxyl groups and has general structure of either (3-propanol)dimethoxyphenol ($\text{C}_{11}\text{H}_{14}\text{O}_4$) or (2-hydroxyacetyl)dimethoxyphenol ($\text{C}_{10}\text{H}_{12}\text{O}_5$). Only the latter structure is consistent with the observation that the peak A compound is more polar than AS, as it elutes before AS on RPC/FPLC

Table 1 Biological activity of derivatives of acetosyringone

a acetosyringone		110	109	93	29
b acetovanillone		80	33	1.9	1.6
c 3,5-dimethoxy acetophenone		ND	1.0	ND	ND
d 4-hydroxy acetophenone		ND	1.1	ND	ND
e syringaldehyde		86	51	2.2	ND
f syringic acid		21	8.6	1.7	ND
g sinapinic acid		104	98	68	18

Acetosyringone (**a**) and six related compounds; acetovanillone (**b**); 3,5-dimethoxy acetophenone (**c**); 4-hydroxyacetophenone (**d**); syringaldehyde (**e**); syringic acid (**f**); and sinapinic acid (**g**), were tested for their ability to induce β -galactosidase in the *Agrobacterium virB::lacZ* strain A348(pSM30). All compounds were purchased from Janssen Chemica, and prepared as 0.1 M solutions in dimethyl sulphoxide. Each compound was serially diluted into MSSP (Fig. 1, legend) medium to 200, 50, 5 and 0.5 μ M (**a**, **b**, **e**, **f**, **g**), or 50 μ M (**c**, **d**). These solutions were inoculated with bacteria at 0.05 absorbance unit ml^{-1} at 600 nm cm^{-1} and incubated at 28 °C, 200 r.p.m. After 12 h, the bacterial β -galactosidase activity in each sample was determined. The data are expressed as activity of the bacteria incubated in the presence of a compound relative to the basal activity present in bacteria incubated without added compound. The basal activity for the pSM30 strain is 10 U. ND, not determined.

(Fig. 1). (2) Comparison of the ultraviolet adsorption spectrum of the peak A compound in CH_3OH with its spectrum in $\text{CH}_3\text{OH}/\text{NaOH}$ indicates that, similarly to AS, this molecule exhibits a strong base-induced redshift (Fig. 3c). Thus, compound A contains a phenolic hydroxyl group *para* to a conjugated ring substituent. Furthermore, the absorption spectra of compound A are almost identical to the equivalent spectra of AS; the respective absorption maxima occur at identical wavelengths (the largest maxima occur at 298 nm in CH_3OH and 355 nm in $\text{CH}_3\text{OH}/\text{NaOH}$), although their relative extinction coefficients are different. These similarities strongly indicate that the peak A compound is very closely related to AS. (3) The quantitative *vir*-inducing activity of the peak A compound is approximately equivalent to that of AS (Fig. 1). As described below, the structure/activity specificity of *vir*-induction indicates that only molecules with similar structure to AS induce *vir* expression to high levels (Table 1).

Fig. 4 Comparison of *vir*-inducing activity of purified peak B compound (Fig. 2) and commercially obtained acetosyringone. Vertical axis, β -galactosidase activity (U bacterium $^{-1}$) in the *Agrobacterium virB::lacZ* strain A348(pSM30); lower horizontal axis, relative concentration of purified peak B compound (Fig. 2) or authentic AS (Janssen Chimica) in the inducing medium, measured as absorbance at 298 nm (cm^{-1}). The extinction coefficient of AS at 298 nm is 10,300 (ref. 29); this value was used to calculate the concentration of inducer compound in the inducing medium, indicated by the upper horizontal axis.

Methods. Purified peak B compound and authentic AS were separately dissolved in MSSP to 1.0 absorbance unit ml^{-1} at 298 nm (cm^{-1}), measured against fresh MSSP. Each solution was serially diluted and the resultant samples were inoculated with bacterium at 0.09 absorbance unit ml^{-1} at 600 nm (cm^{-1}). Samples were incubated for 14 h at 28 °C, 200 r.p.m. and the β -galactosidase activity of the bacteria in each sample determined.

Thus, we have identified plant molecules that induce *vir* expression. Our next experiments seek to provide insight into the relationship between these molecules and *Agrobacterium* in nature. For the *Agrobacterium*/plant transformation system to be most efficient, its activation should be limited to the presence of susceptible plant cells. This could be achieved if activation is signalled only by molecules specific to these cells. For instance, such molecules should first, be produced by different types of plant cells, as *Agrobacterium* can transform several different cell types²⁰; second, be specifically synthesized by susceptible plant cells, such as wounded cells; and third, be available to the bacterium in quantities sufficient for efficient activation. The following experiments demonstrate that AS has these properties and that activation of *Agrobacterium* is a highly specific process.

Different plant tissues produce AS/OH-AS

To determine whether AS and OH-AS are specific to roots or whether they are also produced by other plant tissues, we purified and identified the *vir*-inducing activity produced by leaf cells (Fig. 1). Medium in which *N. tabacum* leaves that have been cut into disks have been cultured (*cml*; conditioned medium leaves) contains substantial amounts of inducing activity that completely partitions into chloroform. The RPC/FPLC profile and corresponding bioassay profile of this material (Fig. 1c) show that the *cml* activity fractionates into two peaks that co-elute with OH-AS and AS. Subsequent purification and GC/MS and ultraviolet spectrophotometric analysis of the active molecules in these peaks confirmed that the major *vir*-inducing activity in *cml* is composed of OH-AS and AS (data not shown). Thus, these two compounds are present in the exudates of at least two different plant tissues.

AS and OH-AS are exudate-specific

In the soil, *Agrobacterium* probably detects plant cells through their exudates. To determine whether AS and OH-AS are

exudate-specific we assessed their relative concentrations within the *N. tabacum* leaf disks of Fig. 1C. These disks were extracted with chloroform and the extract was analysed by RPC/FPLC fractionation and corresponding bioassay. The relative concentrations of AS and OH-AS are <0.5% of the organic compounds present in the total leaf disks (data not shown). In comparison, the relative concentrations of these compounds in the *cml* extract is ~25% and greater (Figs 1C, 5A). Thus, AS and OH-AS probably do not leak out of damaged plant cells and are exudate-specific compounds.

Concentration of *vir* inducers in *cmr/cml*

Figure 4 shows the relationship between the concentration of AS (both commercial and *cmr*-purified) and induction of *virB* expression as measured in units of β -galactosidase activity. Under the conditions used, AS at $\geq 10 \mu\text{M}$, and AS at $1.5 \mu\text{M}$, induce maximal (1,200 U) and half-maximal (600 U) expression, respectively. Note that AS induction does not significantly affect cell viability (that is, induction is a non-lethal event), and that concentrations of AS $>200 \mu\text{M}$ are not significantly toxic to the bacteria. Using the dose-response curve of Fig. 4, the concentration of *vir*-inducing compounds in plant-cell exudates relative to AS can be estimated. Our starting *cmr* and *cml* preparations typically induce between 250 and 500 U β -galactosidase activity in A348 (pSM30); this activity approximately corresponds to between 0.5 and $1 \mu\text{M}$ AS.

Biological activity of acetyosyringone

The primary molecular signal for the initiation in *Agrobacterium* of the events of plant cell transformation should induce in the bacterium both the entire *vir* regulon and the initial steps of T-DNA transfer. We determined that AS has these activities. Several *vir::lac* and *pin::lac* *Agrobacterium* strains were incubated in $20 \mu\text{M}$ AS (both commercial and *cmr*-purified) and assayed for β -galactosidase activity. Inductions of all the previously identified inducible *vir* loci (*B*, *C*, *D*, *E*, *G*) and *pinF* was obtained, and the levels of induction were at least 20–50% higher than those stimulated during co-cultivation with plant cell cultures or incubation with *cmr*¹⁷ (data not shown). AS also induces the production of T-DNA intermediates: when bacteria are incubated with $20 \mu\text{M}$ AS for 12–18 h, T-DNA intermediates¹³ are found at a frequency two- to fivefold greater than that obtained following 48-h co-cultivation with protoplasts¹⁷ (data not shown). We have also seen that AS induces the appearance and/or disappearance of several major proteins in *Agrobacterium* (P. Engström, P.Z. and S.E.S., in preparation). Thus, a single compound is sufficient to trigger the complete activation of *vir* and the initial events of T-DNA transfer; and AS (probably OH-AS also) is a primary signal for plant cell transformation by *Agrobacterium*.

Molecular specificity of *vir* induction

Table 1 shows the respective *vir*-inducing activities of AS (*a*) and analogues of AS (*b–g*). These results indicate that *Agrobacterium vir* expression is efficiently induced by molecules that conform to a structure best represented by AS itself, and suggest that *Agrobacterium* has evolved to recognize and respond to AS as a specific signal for the activation of plant cell transformation. For instance, AS without one methoxy group (*b*) has greatly attenuated *vir*-inducing activity, whereas AS without both methoxy groups (*d*) or its hydroxyl group (*c*) is inactive. The acetyl substituent of AS is important for activity. The formyl (*e*) and carboxylic acid (*f*) analogues of AS have attenuated activity, whereas the cinnamic acid analogue of AS, sinapinic acid (*g*), has approximately equivalent activity to AS. This latter result is interesting in that sinapinic acid is a precursor of lignin, an integral cell-wall constituent of all vascular plants (see below).

Wounding stimulates AS/OH-AS production

Although many dicotyledonous plant cells can be transformed by *Agrobacterium*, only cells that have been wounded or traumat-

Fig. 5 Effect of wounding and inhibition of plant cell metabolism on production of AS and OH-AS by plant cells. RPC/FPLC fractionations of equivalent amounts of medium conditioned with: *a*, 1.5-cm-diameter leaf disks; *b*, intact leaves; *c*, same as *a* but with 5 p.p.m. (12.8 μM) cycloheximide (Actidion, 99%; Aldrich Chemicals) added to the medium. After a 72-h incubation, 40 ml of each respective conditioned medium was recovered, filtered through 0.22 μm nitrocellulose and 35 ml extracted with chloroform (Fig. 1), and the organic pellet was resuspended in 400 μl 10% CH_3OH , 0.1% CH_3COOH . We analysed 100 μl of the sample by RPC/FPLC using the conditions described in Fig. 1. The remaining 5 ml of conditioned medium was bioassayed for *vir*-inducing activity; the units of β -galactosidase activity induced by the conditioned media of *a*, *b* and *c* were 565, 135 and 20, respectively.

Methods. Leaves (4 g) excised from 6-week-old *N. tabacum* SR1 plants were treated as described below and incubated in 50 ml MS medium in a 150-ml Petri dish. Care was taken to use visually equivalent leaves in each experiment. *a*, 5–6 1-cm² disks were obtained per leaf; *b*, intact leaves were used; *c*, same as *a* but with 5 p.p.m. (12.8 μM) cycloheximide (Actidion, 99%; Aldrich Chemicals) added to the medium. After a 72-h incubation, 40 ml of each respective conditioned medium was recovered, filtered through 0.22 μm nitrocellulose and 35 ml extracted with chloroform (Fig. 1), and the organic pellet was resuspended in 400 μl 10% CH_3OH , 0.1% CH_3COOH . We analysed 100 μl of the sample by RPC/FPLC using the conditions described in Fig. 1. The remaining 5 ml of conditioned medium was bioassayed for *vir*-inducing activity; the units of β -galactosidase activity induced by the conditioned media of *a*, *b* and *c* were 565, 135 and 20, respectively.

ized are susceptible. Therefore, we tested whether the production of AS and OH-AS is stimulated by plant cell wounding. Figure 5 shows the RPC/FPLC profiles of the organic extracts of *cml* produced by equivalent amounts of *N. tabacum* leaf disks (wounded cells; Fig. 5a) or intact leaves (unwounded; Fig. 5b). Comparison of these profiles indicates that the 'wounded' *cml* contains >10-fold more AS and OH-AS than the 'unwounded' *cml*, demonstrating that wounding stimulates the appearance of these molecules in the cell exudate. The low levels of AS and OH-AS in the 'unwounded' leaf exudate could be caused by the cut stem surfaces of the leaves.

These results do not define which cells of the wounded tissue produce AS and OH-AS. For example, damaged or dead cells could release AS, although such cells are not good targets for

Agrobacterium infection. We tested whether active plant cell metabolism is required for the production of AS by analysing the *cml* produced by leaf disks incubated in cycloheximide. This material does not contain AS and OH-AS (Fig. 5c). These results confirm and extend our previous observation that in plant/*Agrobacterium* co-cultivations only actively growing plant cell cultures are able to stimulate efficient *vir* gene expression¹⁷. Our data concerning the production of AS and OH-AS in total suggest that these compounds are specifically synthesized and exuded by metabolically active wounded cells.

Discussion

The molecules that we have purified signal *Agrobacterium* to activate the expression of its virulence genes, setting in motion a series of molecular events ultimately resulting in the transfer of T-DNA from the bacterium to the plant cell.

Wounded cells are known to be susceptible to *Agrobacterium* infection, perhaps because the intact cell walls of undamaged cells restrict T-DNA transfer, or because T-DNA integration is dependent on host-cell replication and wounding stimulates this replication. Because *Agrobacterium* responds to AS and OH-AS to initiate plant cell transformation, these molecules potentially represent the signal that *Agrobacterium* detects and recognizes in the soil as susceptible plant cells. The presence of AS and OH-AS specifically in the exudates of wounded but actively metabolizing plant tissues supports our hypothesis.

The activation of *Agrobacterium vir* expression by plant signal molecules probably involves at least two steps: extracellular recognition and intracellular response. The first step could depend on the signal molecule acting as a chemical attractant and/or nutritive source for the bacterium. The latter must depend on the ability of the bacterium to convey the information of the signal from outside to inside the cell and to activate *vir* expression. The mechanism of these events is unknown. Induction of the pTiA6 *vir* region is attenuated in *virA* and does not occur in *virG* mutant bacteria (S.E.S., in preparation). Also, the amino-acid sequence of the *virG* gene product is highly homologous with several positive regulatory proteins of *E. coli*²¹. Because AS can cause the induction of the complete *vir* regulon, we suggest that this compound acts to activate allosterically the *virG* protein, which then activates *vir* transcription by directly interacting with *vir* gene promoter sequences. The *virA* protein potentially functions in the initial extracellular/intracellular recognition and/or intracellular transport of the signal molecule.

AS and OH-AS have not previously been identified as natural component of plant cells, suggesting that the appearance of these molecules in nature is not widespread. Thus, these molecules potentially represent to *Agrobacterium* only those cells which are its desired targets. In addition, these or related molecules might also serve to initiate other bacterial/plant interactions in the soil. The observed resistance of most monocotyledonous plants to *Agrobacterium* could result because these

plants do not produce, or only produce in low quantities, *vir* signal molecules. AS and OH-AS could be useful for obtaining *Agrobacterium* transformation of plant species previously seen to be resistant to *Agrobacterium*, and also for the analysis of the initial molecular steps of the T-DNA transfer process.

Although it is important for *Agrobacterium* to detect and respond to such molecules, it is equally important that it does not respond to closely related but functionally different molecules; we have shown that *vir* induction is most efficiently stimulated by AS and by the lignin precursor sinapinic acid. This latter compound is not present in detectable quantities in our exudate preparations; however, sinapinic acid could be present in the soil in exudates of wounded cells in the process of cell-wall rebuilding.

It is interesting to speculate on the function of AS and OH-AS in plants. These compounds are likely products of the shikimic acid biosynthetic pathway that provides the plant cell with the precursors to a broad spectrum of molecules, including the flavonoids, and lignins²²⁻²⁴. These classes of compounds are important to a plant subjected to stress or injury. For example, many flavonoid-derived phytoalexins are potent inhibitors of the growth of invading pathogens²⁵, whereas lignin, a major component of the cell wall, provides a physical barrier to invasion²⁶. Thus, AS and OH-AS could be part of the wound response²⁷ of plant cells. These compounds are potentially toxic to other soil pathogens, and *Agrobacterium* has evolved to be resistant to AS and OH-AS and to use these chemicals to recognize wounded cells. Alternatively, the compounds could be products related to lignin repair in damaged cells.

We propose that there is a continual excretion of wound-related phenolics during growth, caused by abrasion from the soil. *Agrobacterium* may be attracted to plants by recognition of these compounds. However, significant levels of *vir* induction and the events of T-DNA transfer will only occur if signal molecules are present in sufficient concentrations. As the highest concentrations are found at wound sites, *A. tumefaciens* effectively infects only these sites.

We thank Marc Schelfaut and Luc Van Royen (Laboratory of Organic Chemistry, Rijksuniversiteit, Gent) for help with the GC/MS analyses, and Max Tate (Waite Agricultural Research Institute, Adelaide) for suggestions concerning solvent partitioning. We also thank Klaus Hahlbrock (Max-Planck Institute, Köln) for discussion, Ernest T. Wombatt III, Martine De Cock for preparation of the manuscript and Albert Verstraete and Karel Spruyt for preparation of the figures. This work was supported by grants to M.V.M. and J. Schell from the ASLK-Kankerfonds, the Fonds voor Wetenschappelijk Geneeskundig Onderzoek (FGWO 3.0001.82), the Services of the Prime Minister (OOA 12.0561.84), and was carried out under research contract no. GBI-4-017-B (RS) of the Biomolecular Engineering Programme of the Commission of the European Communities. S.E.S. was funded in part by an EMBO short-term fellowship.

The *Drosophila* developmental gene, *engrailed*, encodes a sequence-specific DNA binding activity

Claude Desplan, James Theis & Patrick H. O'Farrell

Department of Biochemistry and Biophysics, University of California, San Francisco, San Francisco, California 94143, USA

Plasmid expression vectors carrying either the entire engrailed coding region or a subfragment including the homoeo box, produce protein fusions having sequence-specific DNA binding activity.

MUTATIONS in *Drosophila* have identified genes that control major steps in development¹⁻³. Some of these mutants, the segmentation mutants, are defective in the processes that subdivide the embryo into the segmented body plan⁴⁻⁷ while others, the homoeotic mutants, improperly specify the developmental fate of particular regions of the fly¹. Garcia-Bellido⁸ suggested that these mutations affect 'selector genes' that act, in those cells in which they are expressed, to select the developmental pathway. It was proposed that they function by controlling 'cytodifferentiation genes'⁸.

A segmentation gene

Each morphologically obvious segment is composed of cells from two distinct lineages termed anterior and posterior compartments^{9,10}. Genetic analysis suggests that the *engrailed* gene product is required to specify cells as members of posterior compartments¹¹⁻¹⁴. As anticipated by the selector gene hypothesis⁸, by 3.5 h of development *engrailed* gene product accumulates in narrow bands corresponding to the primordia of the posterior part of each segment¹⁵⁻¹⁷. Apparently, the

engrailed regulatory activity acts wherever it is expressed to direct cells along a pathway of development suited to cells of posterior compartments⁸. In *engrailed* mutants, the segmental fusions and the failure to specify cells of posterior compartments are thought to result from the absence of this regulator or from alterations in its expression.

Selector genes interact

In addition to *engrailed*, several other *Drosophila* developmental genes are expressed in spatially restricted patterns consistent with their apparent roles in directing particular portions of the developmental programme¹⁵⁻¹⁹. These studies have focused interest on two related issues. How are these genes regulated to achieve the appropriate pattern of expression, and how do they regulate subsequent development? Recent studies suggest that the selector genes interact in a complex regulatory network. Based on phenotypes of double mutant combinations, Struhl²⁰ argued that the *Ubx* gene product represses *Scr* expression in the mesothorax. Molecular studies²¹ have offered further suggestions of interactions. Regulatory interactions among six different

Fig. 1 Construction of *lacZ-engrailed* fusions and expression in *Escherichia coli*. *a*, Gene fusions; *b*, polyacrylamide gel electrophoresis of bacterial extracts; FL, full-length fusion; HD, homoeo domain fusion; NHD, non-homoeo domain fusion; *lacZ*, β -galactosidase.

Methods: *a*, DNA fragments derived from the *engrailed* locus^{17,35,36} were inserted in the polylinker of expression vector plasmids pUR 290, 291 or 292 (ref. 47). These different plasmids allow inserted DNA to be expressed as a C-terminal extension of β -galactosidase. In the full-length fusion protein (FL) the extension includes 7 amino acids that precede the first methionine of the *engrailed* protein as well as the entire *engrailed* protein. In the homoeo domain construct (HD), a *Bam*HI fragment was spliced out of the FL construction, keeping only the last quarter of the *engrailed* coding sequence from amino acid 409 to the end. This fusion protein contains the entire homoeo domain (amino acids 453-513). Amino acids 347-542, containing the homoeo domain, have been deleted in the non-homoeo domain protein (NHD) by removing a *Xho*I fragment from the FL construct. In the absence of insertion the *lacZ* gene is expressed as the complete β -galactosidase. *b*, Polyacrylamide gel electrophoresis of bacterial extracts. The expression of the fusion proteins from chimaeric plasmids is under the control of the *lac* promoter in a *lacI* overproducing strain DG101 (a gift from D. Gelfand, Cetus Corporation). Bacteria in exponential growth were induced with isopropyl β -thiogalactoside at an absorbance of 0.5 (at 600 nm) and collected 2 h later. Cells were resuspended in about 0.005 culture volume of 25% sucrose, 0.2 mM EDTA, 40 mM Tris-HCl pH 7.5 and 1 mM dithiothreitol (DTT). Lysis and protein solubilization were achieved by lysozyme treatment (0.4 mg ml⁻¹ for 1 h at 0 °C followed by addition of urea to 4 M and further incubation at 0 °C for 1 h). After centrifugation at 20,000 r.p.m. for 1 h the urea was removed from the supernatant by dialysis first against 10 mM Tris-HCl pH 7.5, 25 mM NaCl, 1 mM EDTA, 0.1% Triton X-100, 1 mM DTT, 10% glycerol, 1 mM phenylmethylsulphonyl fluoride, and 0.1 mM benzamidinium containing 2 M urea and subsequently against the same buffer without urea. Glycerol was added to the extracts to a final concentration of 50% and they were stored at -20 °C. When analysed by SDS-gel electrophoresis the fusion proteins are seen as abundant high relative molecular mass proteins (arrowheads). The larger fusion protein is present in lower amounts and we detect numerous minor bands that are presumed to result from degradation of the fusion proteins.

homoeotic loci appear to coordinate their spatial patterns of expression (ref. 22 and C. Wedeen and M. Levine, personal communication).

Recent molecular analyses suggest that the segmentation genes interact to control the expression of one another. Immunofluorescent staining revealed that *engrailed* protein appears first in alternate segments and only later in every segment¹⁷. This led to the suggestion that *engrailed* expression is regulated by the products of another class of segmentation genes, the pair-rule genes^{17,23}, which are expressed in alternate segments^{19,24}. Alterations in the pattern of *engrailed* expression in pair-rule mutants have confirmed this prediction (S. DiNardo and P.H.O'F., unpublished observations; K. Howard and P. Ingham, personal communication). Similar analyses of *fushi tarazu* expression suggest that its expression is also influenced by several other segmentation genes (S. Carroll and M. Scott, personal communication).

These observations suggest an extensive network of regulatory interactions among the *Drosophila* developmental genes, and imply that selector genes are themselves targets for the regulators they encode^{17,23}.

The homoeo box

The products of a number of the developmental genes include a conserved protein domain of 60 amino acids, the homoeo domain. Related sequences have been identified in species from human to annelids²⁵⁻³⁰. This remarkable conservation suggests that the homoeo domain has common physical interactions in all these organisms. A portion of this domain is found in two yeast proteins, $\alpha 1$ and $\alpha 2$, that determine the cell fate (mating type) via transcriptional regulation^{31,32}. Because of this homology it has been proposed that the developmental genes of *Drosophila* might function similarly, by interacting with DNA^{27,33}. Further, it has been noted that sequences within the homoeo domains are compatible with a protein structural motif that characterizes bacterial sequence-specific DNA binding proteins^{27,34}.

Here we address three issues. Does a homoeo-domain-containing protein bind to DNA? Is the binding specific? Is the homoeo domain responsible for binding?

Construction of *engrailed* fusion proteins

To study how the *engrailed* protein product might function as a regulator, we constructed bacterial expression vectors that encoded the *engrailed* protein as carboxy-terminal extensions of β -galactosidase. In order to test for possible autonomous functions of the homoeo domain, we constructed three fusion proteins (Fig. 1). The full-length fusion contained the sequence encoding the entire 552 amino acids of the *engrailed* protein. This *engrailed* protein sequence has been derived from an open reading frame in the *engrailed* cDNA sequence³⁵. The pattern of evolutionary sequence conservation of this open reading frame suggests that it encodes protein (J. Kassis, D. K. Wright, and P.H.O'F., unpublished observations). We think that this predicted protein is made *in vivo* because two antisera directed against different domains of this predicted sequence detect expression of these domains in the posterior compartments of segments¹⁷. The 'homoeo domain fusion' includes only the terminal quarter of the protein coding sequence, encompassing the 60-amino-acid homoeo domain and an additional 44 amino acids on the N-terminal side plus 39 amino acids on the C-terminal side. The 'non-homoeo domain fusion' is deleted for a 196-amino-acid region and lacks the homoeo domain (Fig. 1).

Nonspecific DNA binding

We first tested whether the fusion proteins would bind DNA nonspecifically. We mixed the fusion proteins with labelled restriction fragments of DNA and then, using an antibody directed against bacterial β -galactosidase and fixed *Staphylococcus aureus* as an immunoadsorbent, we precipitated the fusion protein along with bound DNA fragments^{31,36}. The bound DNA fragments were then separated by electrophoresis and detected

Fig. 2 Nonspecific binding of the fusion proteins to DNA. Bacteriophage Φ X174 DNA was cleaved by *Hae*III and end-labelled using T4 polymerase⁴⁸. The labelled DNA (about 30 ng) was incubated for 30 min at 0 °C in 25 μ l of binding buffer (BB) (50 mM NaCl, 20 mM Tris pH 7.6, 0.25 mM EDTA, 1 mM DTT, 10% glycerol) in the presence of a bacterial extract containing the fusion protein (about 10 μ g of total protein extract, see Fig. 1 legend). The complexes formed between DNA and the fusion proteins were then immunoprecipitated by 30 min further incubation at 0 °C with an anti- β -galactosidase monoclonal antibody (provided by Tom Ma-on and Judy Partaledis, courtesy of Mike Hall) preadsorbed on cross-linked *Staphylococcus* (Pansorbin, Calbiochem). The pellet was washed twice in BB, phenol extracted and the DNA ethanol precipitated before polyacrylamide gel electrophoresis and autoradiography. The autoradiogram shows the results of precipitations performed in the presence of extracts containing the full-length fusion (FL), the homoeo domain fusion (HD), the non-homoeo domain fusion (NHD) or β -galactosidase (*lacZ*). Lane T shows the labelled digest before immunoprecipitation, representing 25% of the counts added to the incubation mixture in the immunoprecipitation experiments.

by autoradiography. At low salt concentration (50 mM NaCl) and in the absence of carrier DNA, the full-length fusion protein and the homoeo domain fusion protein bound all of the *Hae*III restriction fragments of bacteriophage Φ X174 DNA, whereas neither β -galactosidase alone, nor the non-homoeo domain fusion protein bound significant amounts of DNA (Fig. 2). Though these observations are consistent with the hypothesis that the homoeo domain would function in DNA binding, the results could potentially be due to simple ionic interactions. Sequence-specific binding would suggest that the fusion protein has a DNA binding domain.

Sequence-specific DNA binding

Since we had no knowledge of what the target sequences for binding of *engrailed* protein might be, we sought a generalized approach to detect sequence specificity. Sequence-specific DNA binding proteins recognize degenerate versions of a consensus binding site. Sufficiently complex DNA should contain, by chance, sequences recognized by the protein. For example, Ross and Landy³⁷ identified the sequence of several binding sites for λ integrase (Int protein) in pBR322 DNA.

To pursue this approach, we digested λ -phage DNA to produce more than 100 fragments and labelled their 3' ends. This DNA was used in the assay described above, except that we added increasing amounts of salt or carrier DNA so that only fragments that bound to the fusion proteins with higher affinities would appear in the precipitate. Figure 3 shows that at low concentrations of carrier DNA all the λ DNA fragments are bound nonselectively (lanes 2, 5), but as the stringency of the

Fig. 3 Sequence-specific DNA interaction of the fusion protein with bacteriophage λ DNA fragments. Bacteriophage λ DNA was restricted with *Sau*3A and labelled using T4 polymerase⁴⁸. Binding assays were performed as described in Fig. 2 legend with the addition of carrier DNA as indicated. Fragments were separated on a 5% polyacrylamide gel. Lane 1 shows the total digest. The amount of DNA loaded in lane 1 is one-quarter of the input amount used in the binding assays (10 ng; $0.4 \mu\text{g ml}^{-1}$). Lanes 2, 3 and 4 show immunoprecipitates obtained following addition of the full-length fusion extract in the presence of 0, 4 and $40 \mu\text{g ml}^{-1}$ of carrier DNA (fragmented calf thymus DNA), respectively. Lanes 5, 6 and 7 show the results of a similar experiment using the homoeo domain fusion extract. Lanes 4 and 7 were exposed four times longer because of the reduced recovery of bands at high levels of carrier.

binding conditions is increased the binding becomes selective. For example, at high concentration of carrier DNA (Fig. 3, lanes 4, 7), only 4 fragments out of 115 DNA fragments are retained. These experiments demonstrate the specificity of *engrailed* fusion protein binding to DNA.

Whether the homoeo domain fusion or the full-length fusion is used in binding assays, the same fragments are recovered in immunoprecipitates at comparable efficiencies (Fig. 3). Thus, the two fusions bind with the same specificity and generally exhibit similar relative affinities for these fragments. The 143 amino acids of the *engrailed* sequence present in the homoeo domain fusion must include a domain competent in specific binding. At least under the conditions of our assay, the additional 409 amino acids of the full-length fusion protein make little or no contribution to the specificity of binding.

To estimate the minimal binding constant of the binding interaction, we assume that all of the fusion protein is active^{31,36}. When our binding assay contains less than 10^{-8} M fusion protein and less than 10^{-11} M DNA fragments, recovery of specific DNA fragments in the immunoprecipitate exceeds 50% (for example Fig. 4A, *engrailed* fragments f and k). Accordingly, the binding constant must exceed $5 \times 10^7 \text{ mol}^{-1}$ (at 170 mM NaCl). Furthermore, preliminary evidence indicating that only a fraction of the fusion protein is active (J.T., unpublished observations) suggests that the binding constant must be higher, and may well be comparable to the binding constants of other sequence-specific DNA binding proteins³⁴.

The binding behaviour of the fusion protein described here may not accurately reproduce the behaviour and specificities of the natural *engrailed* protein. The binding specificity might be influenced by interactions that the fusion protein cannot reproduce or by modifications that would be missing in a protein produced in *Escherichia coli*. Furthermore, our simple *in vitro* binding assay may lack accessory factors that influence *in vivo* binding of the *engrailed* protein to DNA. Nonetheless, because other work using fusion proteins or proteolytic fragments^{31,34} suggests that DNA binding domains can function relatively autonomously, we believe that the results reported here are likely to reflect at least a subset of the activities of the normal *engrailed* protein.

Specific binding to *Drosophila* DNA

If *engrailed* and other selector genes act as pleiotropic regulators of transcription, we might expect their protein products to interact with DNA near the promoters of a number of target genes. Can we identify any plausible candidates for target genes? There is considerable evidence that selector genes regulate each other's expression (summarized above). Thus, we envision that the developmental genes will include regulatory sites that are targets for interaction with the products of other developmental genes. Because of the high degree of relatedness of the developmental genes, the various target sites might also be homologous. Because it is a member of this group of related proteins, perhaps the *engrailed* fusion protein will exhibit site-specific interaction with all or a subset of the related regulatory sites.

Following this line of logic, we decided to look for *engrailed* fusion protein binding adjacent to cloned selector genes. Because a detailed analysis would require DNA sequence information, we chose to examine the *engrailed* locus itself, for which we have 1.2 kilobases (kb) of upstream sequence (unpublished data), and the *fushi tarazu* locus that had been sequenced by Laughon and Scott²⁷.

We looked for *engrailed* fusion protein binding to a 4.9-kb *Eco*RI fragment that includes 2.6 kb of *engrailed* coding sequence and 2.3 kb of upstream sequences³⁸ and to a 3.2-kb fragment that includes the *fushi tarazu* coding sequence and flanking sequences⁴⁹. Figure 4A shows that both the cloned *engrailed* sequences and cloned *fushi tarazu* sequences contain fragments that bind to the *engrailed* fusion protein under stringent assay conditions. In fact, a number of binding fragments are detected (Fig. 4A, C). The positions of binding fragments are indicated in Fig. 4B.

We purified the subfragments indicated by the hatched lines in Fig. 4B and used these to map more precisely the binding interactions upstream of the *engrailed* and *fushi tarazu* coding regions. Secondary digests of these fragments were tested for interactions with the *engrailed* fusion protein (Fig. 5). These analyses localized three binding sites within the 900-base-pair (bp) region 5' to the *engrailed* cDNA. The higher resolution and sensitivity of these experiments showed that the binding fragment k (Fig. 4A, B) actually contained two binding sites (sites a and b in Fig. 5) and that fragment d, though not detected as a binding fragment in experiments using the whole plasmid, contains a weak binding site (site c in Fig. 5). The analysis of the *fushi tarazu* subfragment did not reveal any new binding sites but did contribute to more accurate localization of the upstream site (Fig. 5). At present the accuracy of localization of the sites does not allow us to identify a consensus binding site unambiguously.

Binding sites

Without a functional assay we cannot directly assess the importance of the binding sites detected in cloned *Drosophila* sequences. However, we can test whether affinities, frequency of occurrence, clustering and location of binding sites differ from fortuitous sites.

If the frequency of fortuitous sites were extremely low (less than 1 per 1,000 kb), the presence of a cluster of binding sites within a few kilobases of *engrailed* DNA would be highly significant. This is not the case. Although the frequency of binding sites on a 4.9-kb fragment of *engrailed* DNA is higher than the density of λ DNA, the difference was not very large—about 10-fold (Fig. 4C).

Fortuitous binding sites should have a wide range of affinities depending on their similarity to an optimal site. Higher-affinity fortuitous sites should be less frequent (chance might produce an optimal binding site but should do so less frequently than imprecise approximations of this sequence). We tested the relative affinity of the *engrailed* fusion protein for various binding sites. We used conditions where a number of labelled restriction fragments are bound selectively. Addition of cold competitor DNA displaced bacteriophage λ DNA fragments with different

Fig. 4 Sequence-specific interaction of the homoeo domain fusion protein with restriction fragments of cloned *fushi tarazu* and *engrailed* sequences. The *fushi tarazu* clone (p6-3, derived from clone pDm439, a gift from Matt Scott)⁴⁹ contains 900 bp of upstream sequence, the entire coding sequence and 800 bp of downstream sequence. The *engrailed* clone (p615) contains 2.3 kb of upstream sequence, the complete first exon and most of the first intron^{35,38} (panel B). Restriction fragments of p6-3, p615 or λ DNA were end-labelled and tested for fusion protein binding as described in the legend for Fig. 2, except that a higher salt concentration (170 mM NaCl) was used to diminish nonspecific interactions. Fragments were separated on a 5% acrylamide gel. In the example shown in A, the *fushi tarazu* plasmid (ftz) DNA was digested with *RsaI* and the *engrailed* plasmid (en) was digested with *HinfI* and *ClaI*. Lanes marked T show the total fragment pattern and lanes marked I show the fragments recovered in the immunoprecipitate. For both plasmids the amount of DNA loaded in T is one-quarter of the amount subjected to immunoprecipitation and displayed in I. Bands derived totally from plasmid sequences are identified with a 'p'. Bands derived at least in part from insert sequences are designated as a to j (ftz) or a to o (en) and their positions within the cloned sequence are indicated in B. Similar experiments using *AluI*, *HaeIII*, *BstNI*, *DdeI* or *HpaII* to digest these plasmids gave comparable results (not shown). B shows a map of the inserts in p6-3 (ftz) and p615 (en). The orientation of the coding region within the insert is indicated. Except for the dashed portion of the *engrailed* insert, the sequence is known (refs 27, 35, and J. Kassiss, D. K. Wright and C.D., unpublished). The positions of restriction enzyme sites (*RsaI* sites in ftz and *HinfI* and *ClaI* sites in en) are indicated and all fragments detectable in the separation shown in panel A are lettered. Those fragments detected as bound by the homoeo domain fusion protein are indicated as +. Because they were not detected, a few small restriction fragments (unlettered) could not be scored in the binding experiment (A) but analysis of these DNAs cleaved with other restriction enzymes failed to detect additional binding sites. Exons of the transcribed region are indicated with a bold line and introns with sloping lines. The hatched region indicates the position of a subfragment that was purified and used for additional binding studies (Fig. 5). Note that the region responsible for binding of ftz fragment a, was further localized by analysis of *AluI*, *HaeIII*, *BstNI*, *DdeI*, *HpaII* and *HinfI* digests that defined only one site; this site corresponds to that mapped in more detail by analysis of the purified subfragment (Fig. 5). C Compares the efficiency of homoeo domain fusion protein binding to *engrailed* or λ sites. The binding assays were performed as described in A except that increasing amounts of unlabelled DNA (*HinfI*-restricted p615) was added as competitor. Lanes T represent 10% of the counts of the total digest submitted to immunoprecipitation in lanes 1, 2, 3 and 4. In lane 1, no unlabelled DNA was added while in lanes 2, 3 and 4, 30 ng, 250 ng and 4 μ g, respectively, were added. en lanes: plasmid p615 was restricted with *ClaI* and *HinfI*, labelled and submitted to immunoprecipitation. Lanes 1, 2, 3 and 4 represent immunoprecipitated DNA from ~4 ng of labelled DNA (~1 fmol). Obviously the four bands retained in A behave differently when unlabelled competitor DNA is added. Three bands (arrows) corresponding to fragments f, k and h in A, are detected in the immunoprecipitate in the presence of 1,000-fold excess of unlabelled DNA. λ lanes: λ DNA was restricted with *ClaI* and *HinfI*, labelled and processed under the same conditions as for en DNA. An equimolar amount of DNA (1 fmol) was used in this experiment (20 ng). Two bands were retained at the highest stringency (arrowheads). en + λ lanes: T is an equimolar mixture of en and λ DNA restricted with *ClaI* and *HinfI*. The bands that are retained are the same as those seen in the experiments testing en and λ DNAs individually. Five bands are retained in the presence of the highest concentration of competitor (arrows and arrowheads).

efficiencies (Fig. 4C). Thus, as expected, the binding sites in λ DNA have a range of affinities and there are few high-affinity sites. Assuming that the binding sites in λ DNA occur by chance, the specific binding of 14 restriction fragments at intermediate stringencies suggests that the sequence recognized by the *engrailed* fusion protein is relatively short (about 6 bp) or substantially degenerate.

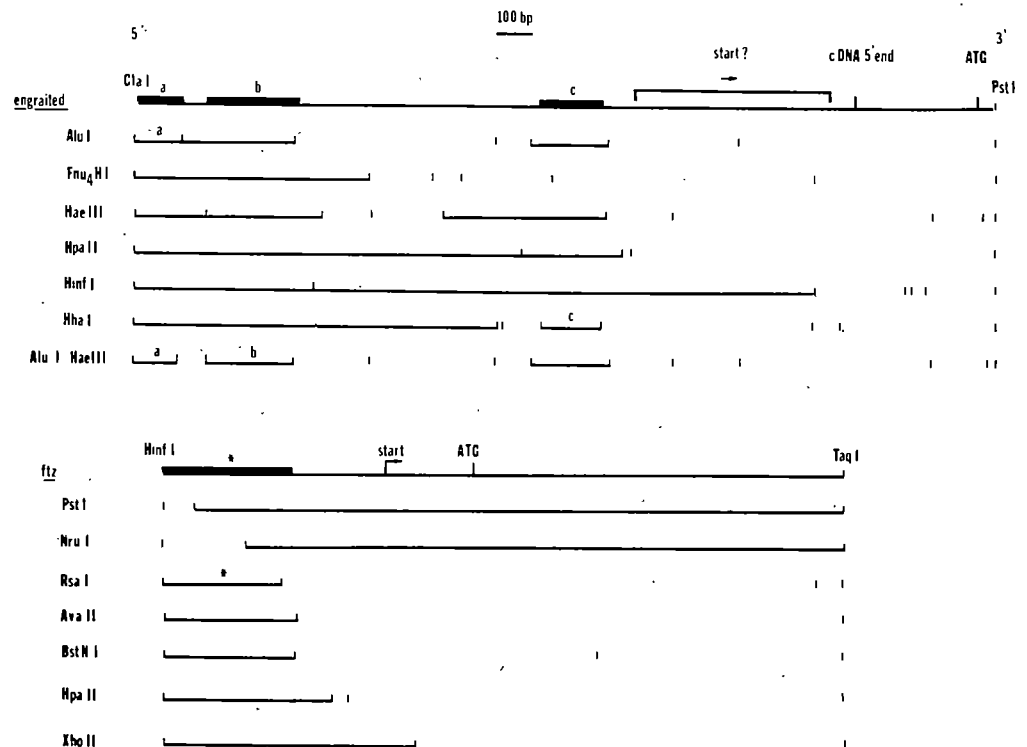

For some sequence-specific DNA binding proteins (such as *lac* repressor), fortuitous occurrence of high-affinity binding sites is extremely unlikely. For these a site of functional interaction (the *lac* operator³⁹) has a distinctively high affinity. For other sequence-specific interactions (for example λ integrase^{37,40}) the affinities of fortuitous and functional sites overlap. Depending on the characteristics of the *engrailed* fusion protein, functionally relevant sites might have distinctively high affinities. We therefore examined the relative binding affinity of *engrailed* and bacteriophage λ DNA fragments. We observe differing affinities for the *engrailed* fusion protein interaction with various sites on *engrailed* DNA (Fig. 4C). Using our present assay, the ranges of affinities seen for λ and *engrailed* sites overlap (Fig. 4C). Three *engrailed* fragments bind with

particularly high affinity (arrows) compared with two λ fragments (arrowheads).

The binding data provide no support for suggestions that the binding sites in *Drosophila* DNA are functional. It should, however, be made clear that the opposing conclusion also cannot be reached from these data; that is, the binding sites in *engrailed* DNA cannot be dismissed as nonfunctional because they have properties similar to fortuitous binding sites. Thus, the issue of function remains open.

Although the functional importance of the binding sites still requires experimental test, we propose that the binding sites we have detected in *Drosophila* DNA function *in vivo* as targets for interaction with either the *engrailed* protein or closely related gene products (that is, other selector genes). We make this suggestion on the basis of the location, clustering and conservation of the sites. The positions of binding sites in relation to the *fushi tarazu* and the *engrailed* coding regions are reminiscent of the positions of enhancer elements in other systems⁴¹⁻⁴³. The clustering of binding sites is unlikely to be coincidental. Such clustering of binding sites for regulatory proteins is fairly common (for example, refs 44, 45). Finally, if functional, the binding

Fig. 5 Localization of binding sites in the 5' regions of *engrailed* and *fushi tarazu*. In digests of whole plasmid DNA we identified fragments that were bound by the homoeo domain fusion protein (Fig. 4). To localize more precisely the binding sites immediately upstream of the *engrailed* and *fushi tarazu* coding regions, we purified a 1,180-bp *Clal*-*PstI* fragment from the *engrailed* clone and a 939-bp *HinfI*-*TaqI* fragment from the *fushi tarazu* clone (Fig. 4B). These purified fragments were digested with additional enzymes as indicated and the binding of subfragments assayed as before (Fig. 4). In each of the restriction digests shown here the binding fragments are indicated as solid lines. Although the overlap of binding sites: a *Clal*-*AluI* fragment (a, the binding regions, this could be misleading if the binding sites were complex. Therefore, in the summary diagrams above the restriction patterns, we have indicated the precision of the localization of the binding sites based on the minimal fragment showing binding (bold line). For *engrailed*, three fragments were identified as containing binding sites: a, *Clal*-*AluI* fragment (a, 67 bp), a *HaeIII*-*AluI* fragment (b, 100 bp) and a *HhaI* fragment (c, 88 bp). For *ftz* a single site was localized to a 165-bp *HinfI*-*RsaI* fragment(*).

sites will be conserved in evolution. In the absence of a functional test, we believe that the best way to distinguish fortuitous and functional binding sites is to see whether protein binding occurs at analogous positions in distantly related genomes. We have cloned the *engrailed* gene of a distantly related *Drosophila* species, *D. virilis*⁴⁶. A preliminary analysis indicates that the fusion protein binds to fragments upstream of the *D. virilis* *engrailed* gene (D. Wright, unpublished data).

Binding specificity

Together with previous arguments²⁷, our results predict that the homoeo domain imparts a sequence-specific DNA binding activity to the protein. Accordingly, other homoeo domain-containing proteins should also bind DNA in a sequence-specific manner and such proteins having closely homologous homoeo domains should have similar sequence specificity. We presently recognize two classes of homoeo domain sequences. Class I is comprised of seven genes which have highly homologous homoeo domains and are located in two clusters of developmental genes (the bithorax complex and the *Antennapedia* complex)^{22,25}. Class II is comprised of the *engrailed* homoeo domain and the highly homologous homoeo domain of the *engrailed* related gene³⁵. The homoeo domains of different classes have lower homology (Fig. 6). As noted previously, the regions of sequence identity suggest that class I homoeo domains might specify binding to the same sequence²⁷. The differences between class I and class II homoeo domains might include an alteration of the sequence specificity.

Evolution of proteins

Duplication and divergence of a primordial gene encoding a DNA binding protein might lead to a family of interacting regulators. If the primordial protein included sequences for dimerization and for DNA binding, newly duplicated coding regions would have common binding specificities and could form heterotypic dimers. The interactions between products of duplicated genes would persist if the dimerization function and DNA binding function were conserved. We suggest that continued duplication and divergence can result in a family of DNA binding proteins that interact physically by forming heterotypic associations and interact functionally by competition for binding

to related DNA binding sites. Such interactions would link the various genes in a regulatory network. The evolution of the members of the family would be coupled because of the importance of maintaining the interactions among the members of this regulatory network. Since coordinate change of many genes is an extraordinarily unlikely event, such a network of interaction

Fig. 6 Family tree of relatedness of homoeo domains. Pairwise comparisons of the protein sequences of the homoeo domains encoded by *Drosophila* genes (*Antp*, *Ubx*, *ftz*, *en* and *er*), yeast genes (*a1* and *a2*) and sequences isolated by homology from humans (*Hu1* and *Hu2*) and frogs (*AC1*) were used to score divergence. The comparison was confined to residues 29-58 because this region is well conserved among all of these sequences. To produce homology scores we gave one point for amino-acid identity and half a point for similarity. The data are assembled into a family tree by indicating the divergence of each sequence that approximates all the pairwise comparisons. The sequence data are taken from Levine *et al.*²⁸ (*Hu1* and *Hu2*), Scott and Weiner²⁶ (*Ubx* and *ftz*), McGinnis *et al.*²⁵ (*Antp*), Poole *et al.*³⁵ (*en* and *er*), Carrasco *et al.*³⁰ (*AC1*), and Tatchell *et al.*³² (*a2* and *a1*). Note that the discrepancies in the published sequence^{25,26} for *Ubx* are significant in comparison to the divergence among class I homoeo domains.

may contribute to the extraordinary conservation of homoeo domain sequences. It should be possible to test the predictions of this rationale using approaches similar to those used here to show that the *engrailed* gene encodes a sequence-specific DNA binding activity.

We thank our colleagues for discussions and experimental assistance, particularly Steve DiNardo, Mike Hall, Sandy Johnson, Judy Kassis, Jerry Kuner, Roger Miesfield, Sandro

Rusconi, Elizabeth Sher and Deann Wright. We thank Steve Poole for the gift of *en* cDNA and sequence information before publication, Matt Scott for the *fushi tarazu* clone and for encouragement, and Sandy Johnson and Keith Yamamoto for their comments on the manuscript. This work was funded by NSF grant PCM-8418263 and by NIH grant GM 31286. C.D. was supported by a Fogarty fellowship and by ARC, and J.T. by an NIH training grant.

Identification of complementary DNAs encoding the human glucocorticoid receptor predicts two protein forms, of 777 (α) and 742 (β) amino acids, which differ at their carboxy termini. The proteins contain a cysteine/lysine/arginine-rich region which may define the DNA-binding domain. Pure radiolabelled glucocorticoid receptor, synthesized in vitro, is immuno-reactive and possesses intrinsic steroid-binding activity characteristic of the native glucocorticoid receptor.

TRANSCRIPTIONAL regulation of development and homeostasis is controlled in complex eukaryotes by a wide variety of regulatory substances, including steroid hormones. The latter exert potent effects on development and differentiation in phylogenetically diverse organisms and their actions are mediated as a consequence of their interactions with specific, high-affinity binding proteins referred to as receptors¹⁻⁶. Many of the primary effects of steroid hormones involve increased transcription of a subset of genes in specific cell types^{7,8}. The structural characterization of the steroid receptor protein and the definition of the molecular actions of the steroid hormone/receptor complex would help to define the biochemical events which modulate gene transcription. A series of receptor proteins, each specific for one of several known steroid hormones, are distributed in

a tissue-specific fashion, although many cell types simultaneously express receptors for several steroid hormones^{9,10}. It is postulated that steroids enter cells by facilitated diffusion and bind to the specific receptor protein, initiating an allosteric alteration of the complex. As a result of this transformation, the steroid hormone/receptor complex appears capable of binding high-affinity sites on chromatin and modulating transcription of specific genes by a mechanistically unknown process^{11,12}.

The glucocorticoid receptor is widely distributed and expressed in many cultured cell lines, and the control of gene expression by glucocorticoids, therefore, has been widely studied as a model for transcriptional regulation. A number of glucocorticoid-responsive transcriptional units, including mouse mammary tumour virus (MMTV)^{13,14}, mouse and human metal-

Fig. 1 Human glucocorticoid receptor cDNA sequencing strategy and schematic representation of cDNA clones. **a**, The composite cDNA for the α glucocorticoid receptor is represented at the top, with noncoding (lines) and coding (stippled portion) sequences indicated. Common 6-nucleotide restriction enzyme sites are shown. Overlapping cDNA inserts used to determine the sequence are shown: arrows beneath the regions sequenced show the direction and extent of sequencing. The dashed line at the 3' end of OB10 indicates divergent sequence. Numbers refer to nucleotide positions in OB10 relative to the 5'-most transcribed sequence. **b**, cDNAs encoding the α and β forms of the receptor (OB7 and OB10, respectively). The 5' end of OB7 (broken lines) is contributed by the OB10 clone. Protein-coding information is represented by wide bars; untranslated sequences are indicated by thin bars. Nucleotides and amino acids are numbered above and below the coding sequence, respectively. Common DNA sequences extend to nucleotide 2,313 (amino-acid residue 727), at which point the α - and β -receptor forms diverge, with the α cDNAs (OB12, OB7) continuing in an open reading frame for 150 nucleotides (50 amino acids) and the β cDNA (OB10) continuing for 45 nucleotides (15 amino acids; see Fig. 3). Hexanucleotide signals (AATAAA) just upstream of the poly(A) in the clones are indicated, with the first hexanucleotide in OB7 serving as poly(A) in OB12.

Methods. The inserts hGR1.2, hGR2.9 and hGR5.16 were isolated from a λ gt11 IM-9 lymphoid cell cDNA library as described previously⁴². Two clones were isolated from cDNA libraries constructed by H. Okayama in pcD (ref. 44) using poly(A)⁺ mRNA from GM637 human fibroblasts (OB7) and primary human fibroblasts (OB10). Screening was performed with the hGR1.2 cDNA, radiolabelled by nick-translation with ³²P-dCTP. Sequences were determined by the chemical cleavage method of Maxam and Gilbert⁴⁵.

lothionein^{15,16}, rat α_2 -globulin¹⁷ and rat and human growth hormone¹⁸⁻²⁰ genes have been identified. DNA sequences mediating transcriptional stimulation of several of these genes have been localized. For MMTV, these sequences are discrete genomic regions upstream of the transcriptional start site which appear to exert their actions independently of orientation and position^{21,22}. The steroid/receptor complex appears to bind to these regulatory sequences and purified receptor has been used to define the specific binding sites²³⁻²⁶. Based on the footprinting analyses of several responsive genes, a consensus DNA binding sequence sharing the core sequence 5' TGT/CTCT 3' has been proposed²⁷.

The ability of the glucocorticoid-responsive element (GRE) to alter its position and orientation yet still maintain promoter inducibility suggests that it resembles the class of *cis*-acting regulatory sequences termed enhancers²¹. First discovered in viruses and subsequently in cellular genes, these sequences are necessary for efficient transcription *in vivo*²⁸⁻³¹. It has been suggested that enhancers are recognized by *trans*-acting factors that mediate regulatory effects by tissue-specific transcriptional control. Although the enhancer factors have not been well characterized, the glucocorticoid receptor may serve as a paradigm for these putative gene activator proteins.

The availability of radiolabelled high-affinity glucocorticoid analogues such as dexamethasone and triamcinolone acetone has led to the development of purification strategies resulting in the isolation of nearly pure rat and human receptors^{32,33}. Although the receptor migrates as a dimer in sucrose gradients, analysis on denaturing SDS-polyacrylamide gels detects a single polypeptide of relative molecular mass (M_r) ~94,000 (94K)^{34,35}. The native polypeptide contains intrinsic specificity for steroid binding and DNA sequence recognition. By using as probes monoclonal and polyclonal antibodies raised against the purified rat and human receptors³⁶⁻³⁸, it has been possible to identify a major immunogenic region in the receptor residing on a portion of the molecule that is distinct from the steroid- and DNA-binding regions³⁹⁻⁴¹. To gain further information about the structure of this molecule and to begin an analysis of the

molecular mechanisms by which it regulates gene transcription, we set out to clone receptor cDNA sequences. By using receptor-specific antibodies as probes, we and others have isolated clones containing human or rat glucocorticoid receptor cDNA inserts^{42,43}.

Here we report the complete amino-acid sequence of the human glucocorticoid receptor (hGR), deduced from human lymphoid and fibroblast cDNA clones. The sequence reveals various structural features of the receptor, including the major immunogenic domain and a cysteine/arginine/lysine-rich region which may constitute a portion of the DNA-binding domain. We describe the use of the SP6 transcription vector system to generate analytical amounts of full-length protein, and demonstrate that the cell-free translated protein is both immunoreactive and possesses steroid-binding properties characteristic of the native glucocorticoid receptor. An accompanying paper describes the homology of the hGR sequence to that of the oncogene *v-erb-A*⁶⁴.

Glucocorticoid receptor cDNA

A library of cDNA clones was constructed in the phage expression vector λ gt11 using poly(A)⁺ RNA from the human lymphoid cell line IM-9 as template, as described previously⁴². This library was initially screened with a rabbit polyclonal antiserum to the purified glucocorticoid receptor, resulting in the isolation of several immunopositive candidate clones from ~2.5 × 10⁵ plaques. The β -galactosidase fusion proteins generated from these clones were used to affinity-purify receptor epitope-specific antibody, which was subsequently recovered and identified by binding to protein blots of cellular extracts. Three clones containing inserts expressing antigenic determinants of the human glucocorticoid receptor were isolated. The inserts of these clones, although of different sizes, cross-hybridized, indicating that they contained a common sequence which presumably delimits the major immunogenic domain of the receptor. Together, these clones spanned 1.4 kilobase pairs (kbp) but were clearly not long enough to code for the entire

[illegible]

Fig. 2 cDNA and predicted protein sequence of human glucocorticoid receptor. The complete α coding sequence and OB7 3'-untranslated region are shown, with the deduced amino acids given above the long open reading frame. An upstream in-frame stop codon at nucleotides 121-123 and putative additional polyadenylation signals in OB7 are underlined.

receptor, which was estimated to require ~2,500 nucleotides to encode a polypeptide of M_r 94K.

To isolate additional cDNA clones we again screened the original library and also examined a second library (given by H. Okayama) prepared with poly(A)⁺ RNA from human fibro-

lasts in the vector described by Okayama and Berg⁴⁴. Using one of the immunopositive cDNA inserts (hGR1.2) as probe, 12 clones were isolated that, together, covered more than 4.0 kbp. The nucleotide sequences of these clones were determined by the procedure of Maxam and Gilbert⁴⁵ according to the strategy

Fig. 4 Immunoblot comparison of hGR translated *in vitro* with *in vivo* hGR from cell extracts. **a**, The vectors constructed for *in vitro* transcription of the hGR cDNA sequence. The complete α (pGR107) and β (pGR108) coding sequences were placed under the transcriptional control of the SP6 promoter in pGEM1. Vector sequences, noncoding cDNA sequences and coding sequences are indicated by thin lines, thick bars and boxed regions, respectively. The poly(A) tract of ~60 nucleotides is indicated by A_n. Divergent coding sequences are indicated by striped and stippled regions. **b**, Western blot analysis of *in vitro* translation products and cell extracts. Unlabelled translation products synthesized in a rabbit reticulocyte lysate system with no added RNA (lane 1) or with RNA synthesized from pGR108 (β , lane 2) or pGR107 (α , lane 3) were fractionated on a 7.5% SDS-polyacrylamide gel. Additional lanes are: cytoplasmic extracts from IM-9 (lane 4), IM-9 treated with 1 μ M triamcinolone acetonide (lane 5), HeLa (lane 6), ADR6.M1890.AD1 mouse lymphoma (lane 7), S49 mouse lymphoma (lane 8) and EL4 lymphoma (lane 9). Proteins were transferred to nitrocellulose and probed with anti-hGR antibody, followed by ¹²⁵I-labelled *Staphylococcus aureus* protein A as described previously⁴².

Methods. To construct an expression vector containing the entire α coding sequence shown in Fig. 2, the 3' coding sequence of OB7 was fused to OB10 5' coding information. OB7 was partially digested with *Eco*RI, completely digested with *Xba*I, and the 1.2-kbp fragment was gel-purified and ligated with *Eco*RI/*Xba*I-digested OB10 to produce the intermediate pOB107. The entire pOB107 cDNA sequence including the 5' poly(G) tract (11 nucleotides, nt) and 3' poly(A) tract (~60 nt) was excised by partial *Pst*I/complete *Bam*HI digestion. The resultant 3.5-kb fragment was gel-purified and inserted between the *Pst*I and *Bam*HI sites of pGEM1 (Promega Biotec) to yield pGR107. Plasmid GR108 was directly constructed from pOB10 by partial *Pst*I/complete *Bam*HI digestion and insertion of the resulting cDNA insert into the corresponding sites of pGEM1. Capped SP6 transcripts were synthesized from *Pvu*II-linearized pGR107 and pGR108, as described by Krieg and Melton⁶², with simultaneous capping effected by reduction of the GTP concentration from 400 to 100 μ M and addition of m⁷GppG (Pharmacia) to 500 μ M. Transcripts were purified by P60 chromatography and translated with micrococcal nuclease-treated rabbit reticulocyte lysate (Promega Biotec) in conditions suggested by the manufacturer. Preparation of IM-9 cytosol from steroid-treated cells was as described previously⁴². Size markers are phosphorylase B (97K), bovine serum albumin (66K) and ovalbumin (45K).

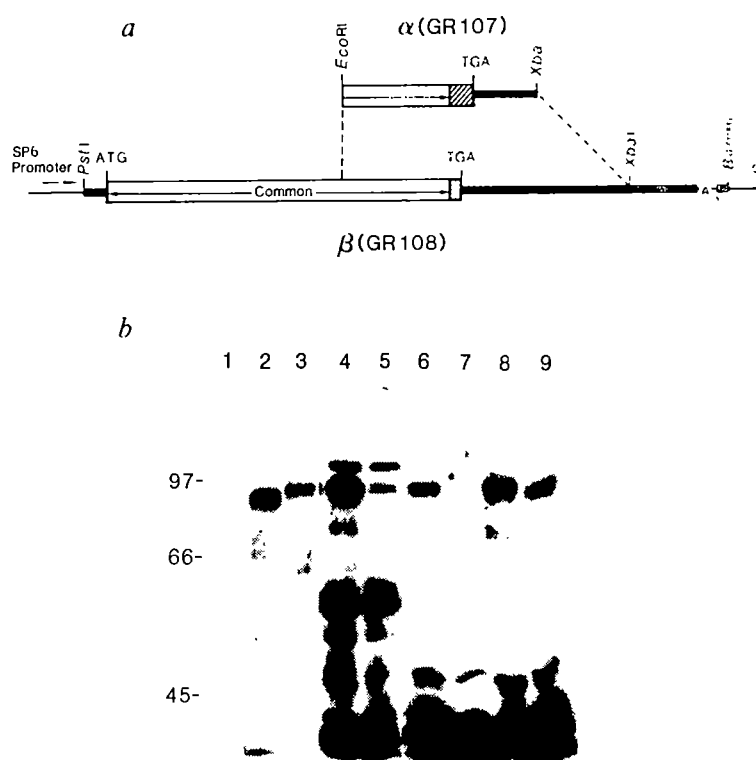

tor cDNA clones and receptor protein by immunoblot analysis, we conclude that the predominant physiological form of the glucocorticoid receptor is the α (94K) species.

Expression of hGR *in vitro*

To provide additional evidence that the cloned receptor is functional, we investigated the possibility that the *in vitro*-translated products might be able to selectively bind corticosteroids. Accordingly, the rabbit reticulocyte lysate was incubated with the radiolabelled synthetic glucocorticoid analogue ³H-triamcinolone acetonide (³H-TA) before or after addition of *in vitro*-synthesized α or β hGR RNA. As shown in Fig. 5, those lysates programmed with α -hGR RNA acquired selective steroid-binding capacity; unexpectedly, the β -receptor synthesized *in vitro* failed to bind competable ³H-TA. The *in vitro*-synthesized α -hGR bound radiolabelled steroid which could be competed with by addition of excess unlabelled cortisol or dexamethasone; however, binding of ³H-TA was not effectively competed with by addition of excess unlabelled oestrogen or testosterone. In contrast, excess progesterone constituted an effective competitor, consistent with the previously reported anti-glucocorticoid activities of progesterone⁴⁷. To confirm these results, the competition experiments were repeated with native glucocorticoid receptor prepared from extracts of human lymphoid cells. Both the *in vitro*-translated receptor and the natural *in vivo* receptor have nearly identical properties with regard to steroid binding and competition with excess unlabelled steroid analogue (Fig. 5).

hGR sequences map to at least two genes

The human glucocorticoid receptor gene has been functionally mapped to chromosome 5. Analysis of somatic cell hybrids constructed by fusing receptor-deficient mouse T cells (EL4)

with human receptor-containing T cells (CEM-C7) indicated that segregants expressing the wild-type CEM-C7 receptor maintained human chromosome 5 while dexamethasone-resistant segregants had lost this chromosome⁴⁸.

To confirm the authenticity of our cDNA clones, we mapped receptor cDNA sequences using Chinese hamster/human somatic cell hybrids containing only human chromosome 5 (HHW454). DNAs extracted from human placenta, HHW454 hybrid cells and Chinese hamster ovary (CHO) cells were digested with *Eco*RI or *Hind*III restriction endonucleases and separated on a 0.8% agarose gel. DNA fragments transferred to nitrocellulose were probed with a portion of the receptor-coding region derived from nucleotides 570-1,640 (hGR1.2A; Fig. 1). In addition to CHO-specific *Eco*RI bands of 6.8 and 17 kbp (Fig. 6a, lanes 2,3), DNA from the hybrid cell line also contains human-specific bands of 3.0 and 5.0 kbp. Unexpectedly, a DNA fragment of 9.5 kbp is found in total human DNA but not in the hybrid line (Fig. 6a, lane 1). Similarly, *Hind*III digestion revealed a 7.5-kbp band that is not present in the chromosome 5 hybrid cell DNA (Fig. 6a, lane 4). These results indicate that the receptor cDNA maps to human chromosome 5, but that there are additional receptor-related sequences elsewhere in the genome. To map these sequences, we used a dual-laser fluorescence-activated cell sorter (FACS) to sort mitotic chromosome suspensions stained with DAPI/chromomycin in conjunction with Hoechst 33258 chromomycin; this technique allows separation of the 24 human chromosome types into 22 fractions⁴⁹. After the chromosomes were sorted directly onto nitrocellulose, the chromosomal DNA was denatured and hybridized to the hGR cDNA probe. In addition to confirming the chromosome 5 localization, additional sequences were found on chromosome 16 (Fig. 6b). To confirm this localization, DNAs from mouse erythroleukaemia cells and a mouse erythroleukaemia cell line containing human chromosome 16 (ref. 50) were digested with

Fig. 5 Steroid-binding of α -hGR (GR107) translated *in vitro*. Binding to IM-9 cytosol extract (stippled bars) and to reticulocyte lysate containing SP6-generated α -hGR RNA (GR107; open bars) are shown. Bars represent bound ^3H -triamcinolone acetonide (TA) determined with a 100-fold excess of various steroid competitors; 100% competition was determined using unlabelled TA as competitor. The values represent the mean of triplicate determinations, with error bars showing $P < 0.05$. Steroid competitors are dexamethasone (Dex), cortisol (Cort), progesterone (Prog), testosterone (Test), and oestradiol (Oest).

Methods. Binding assays were performed in 100 μl containing 10 mM Tris-HCl pH 7.4, 100 mM NaCl, 1 mM EDTA, 10 mM sodium molybdate, 10 dithiothreitol, 150 mM ^3H -TA (20 Ci mmol $^{-1}$; Amersham) and 10 μl translation mixture or 100 μg fresh IM-9 cytosol. Unlabelled steroid competitor (15 μM) was added as indicated. After 2 h at 0 $^{\circ}\text{C}$, samples were extracted twice for 5 min each with 5 μl of 50% dextran-coated charcoal to remove unbound steroid, and counted. Uncompeted and fully competed values for the α glucocorticoid receptor (GR107) were 490 and 290 c.p.m., respectively. Reticulocyte lysate translation mixtures without added transcript or programmed with β -receptor SP6 RNA (GR108) contained no competeable ^3H -TA binding.

*Hind*III and probed with hGR cDNA (Fig. 6c); as predicted, the only DNA fragment found in the hybrid and not in the control was the 7.5-kbp DNA fragment, thus establishing the chromosome 16 assignment (Fig. 6c, lanes 1, 2).

Additional Southern blot analyses using the *Eco*RI-*Xba*I fragments from OB7 and OB10 3'-untranslated regions revealed hybridization only to chromosome 5 (data not shown). We conclude that both the α - and β -receptor cDNAs are probably encoded by a single gene on chromosome 5 and suggest that the two cDNA forms are generated by alternative splicing. In addition, we conclude that another gene residing on human chromosome 16 contains homology to the glucocorticoid receptor gene, at least between nucleotides 570 and 1,640. It is not clear whether these sequences on chromosome 16 represent a related steroid receptor gene, a processed gene or pseudogene, or a gene that shares a common domain with the gene for the glucocorticoid receptor. Genomic cloning and DNA sequencing may provide the answer.

To determine the size of the mRNA encoding the glucocorticoid receptor, Northern blot hybridization⁵¹ experiments were performed using cytoplasmic mRNA isolated from a human fibroblast cell line, HT1080. Using the hGR1.2 coding sequence as probe, multiple mRNAs of 5.6, 6.1 and 7.1 kb were detected. Treatment of these cells with glucocorticoids for 24 h leads to a 2-3-fold reduction in receptor mRNAs, suggesting a potential negative feedback regulation.

Discussion

Structural analysis of the glucocorticoid receptor is a prerequisite for gaining insight into the mechanisms by which this regulatory molecule exerts its effects on gene transcription. Here, we have presented the primary sequence of the human glucocorticoid receptor deduced from nucleotide sequence analysis of cDNA clones.

Isolation of hGR cDNAs has revealed the existence of multiple mRNAs encoding at least two forms of the polypeptide. The predicted proteins differ at their carboxy termini by the substitution of 50 amino acids in the case of α -hGR and 15 amino acids in the case of β -hGR. The α glucocorticoid receptor is the major

Fig. 6 Chromosome mapping analysis of hGR cDNA. **A**, 10 μg of DNA from human placenta (lanes 1, 4), CHO/human somatic cell hybrid (HHW454, lanes 2, 5) containing chromosome 5 as its only human complement, or CHO (lanes 3, 6), was digested with *Eco*RI (lanes 1-3) or *Hind*III (lanes 4-6) to completion, fractionated on a 0.8% agarose gel and transferred to nitrocellulose paper. **B**, Chromosomes (3×10^4) prepared from a human lymphocyte cell line, stained with 4,6-bis(2"-imidazolyl)-4H,5H)-2-phenylindole (DIPI)/chromomycin A3 and sorted using a dual-laser custom FACS IV chromosome sorter⁶³, were denatured and neutralized on nitrocellulose paper. Note that Hoechst/chromomycin-stained chromosome 9 was sorted with chromosomes 10-12. **C**, 10 μg of DNA from the parental mouse cell line MEL (lane 1) or the parentally derived somatic cell hybrid carrying human chromosome 16 (ref. 50; lane 2) was digested with *Hind*III and separated on a 0.8% agarose gel, then transferred to nitrocellulose paper. All filters were probed with the 1,100-bp insert from hGR1.2, nick-translated to a specific activity of 3×10^8 c.p.m. μg^{-1} and hybridized in $5 \times \text{SSPE}$, $1 \times \text{Denhardt's}$, 0.1% SDS, 50% formamide, 100 $\mu\text{g ml}^{-1}$ denatured salmon sperm DNA, 50% dextran sulphate at 42 $^{\circ}\text{C}$ for 18 h. Filters were washed twice (for 30 min each) in $2 \times \text{SSC}$ at 68 $^{\circ}\text{C}$ and exposed to X-ray film at -70 $^{\circ}\text{C}$ with an intensifying screen.

Fig. 7 Northern blot analysis of hGR mRNA. 10 μ g of poly(A)⁺ mRNA from human HT1080 fibroblast cells, collected after 24 h without (–) or with (+) treatment with 10 μ M dexamethasone, was electrophoresed through a 0.8% agarose/1% formaldehyde gel, stained with acridine orange (120 μ g ml^{–1}) and transferred to nitrocellulose. The filter was hybridized overnight with nick-translated hGR1.2 (10⁶ c.p.m. ml^{–1}, specific activity 10⁸ c.p.m. μ g^{–1}) and washed with 2 \times SSC at 68 °C. Sizes were estimated from human fibronectin mRNA (7.8 kb), and 28 S (5.0 kb) and 18 S (2.1 kb) ribosomal RNAs.

form identified in several human cell lines and cDNA libraries. However, a recent report by Northrop *et al.* characterizes two forms of the receptor in mouse lymphoid cells⁵². The relationship of α - and β -hGR to the mouse doublet species remains to be established. Also, the cellular distribution and potential function of β -hGR are unclear, although it is possible that variant receptors are used for tissue-specific functions. We are now generating antisera to synthetic peptides specific for each human receptor form to elucidate their tissue-specific expression.

Among the cDNAs selected using the immunopositive phage DNA insert hGR1.2A as probe were those containing 3' ends similar to OB7, except that polyadenylation was signalled earlier by the use of an AATAAA at nucleotide 3,101. These clones have been isolated from both human fibroblast and placental libraries (data not shown). Alternative poly(A) site selection is a feature of many eukaryotic transcription units⁵³. In some instances, selection of poly(A) sites specifies particular polypeptide products^{54–57} while in other cases, alternative poly(A) site selection produces no change in the primary structure of the polypeptide⁵⁸. The selection of poly(A) sites during receptor transcription may (1) alter the stability of the mRNA in a particular tissue, (2) lead to splicing changes, or (3) be random, with no physiological consequence.

The *in vitro* translation studies described here provide direct evidence that the cloned molecule encodes the complete glucocorticoid receptor. First, the *in vitro*-translated product is identical in size to the native glucocorticoid receptor and is immunologically reactive with receptor-specific antiserum.

Second, the *in vitro*-translated protein acts functionally as a glucocorticoid receptor in that it is capable of selectively binding the synthetic glucocorticoid triamcinolone acetonide. This binding is specifically competed with by glucocorticoids, glucocorticoid analogues and progesterone but is not competed with by the sex steroids testosterone and oestrogen. In this respect, the *in vitro*-translated receptor behaves identically to the *in vivo* receptor from human lymphoid cells, providing the first evidence for a function of the cloned molecule. The acquisition of steroid-binding properties does not appear to require any specific modifications or, if it does, these modifications can occur in the *in vitro* translation mix.

The results presented here provide the information necessary for studying the molecular interactions of a eukaryotic transcriptional regulatory protein with its target genes. These structural studies provide a basis from which the glucocorticoid receptor, its gene, and its RNA products can be analysed. Furthermore, the ability to express receptor *in vitro* provides a novel means by which the consequence of specific *in vitro* mutagenesis can be rapidly tested.

In addition to the *in vitro* studies, the analysis of several existing rodent cell lines^{49,59–61} with well-characterized receptor defects in both the DNA- and steroid-binding domains should facilitate future analysis. Furthermore, the isolation of genes responsive to glucocorticoids and specific regulatory elements by both mutagenic and protein-binding studies suggests that this protein will serve as a very useful model for analysis of inducible eukaryotic gene regulation.

We thank Drs Kelly Mayo, Geoffrey Wahl, Michael Wilson, Noellyn Oliver, Tony Hunter and Donald Gruol for advice and discussion; our collaborator Dr John Wasmuth for providing human/hamster somatic cell hybrids; Hiroto Okayama for providing human fibroblast cDNA libraries; Noellyn Oliver for HT1080 cells; and Kevin Struhl for suggestions on *in vitro* translation studies. We also thank Marijke ter Horst for preparation of artwork and secretarial assistance. The X-ray binary Cygnus X-3 has long been suspected of containing a fast, young pulsar, but previous observations at various wavelengths have failed to provide any evidence of a signal with a periodicity of less than 4.8 h (the well-known periodicity in the X-ray and infrared wavebands which is ascribed to orbital motion of a binary system). Here we report measurements of 1,000-GeV γ -rays which suggest a pulsar period of 12.5908 ± 0.0003 ms, for data recorded in 1983 at the times of X-ray maximum in the 4.8-h cycle. The conservative probability of such a periodicity occurring by chance is 4×10^{-7} and, moreover, supportive evidence is provided by some earlier data.

Cyg X-3 has been observed many times by γ -ray telescopes at TeV energies¹⁻⁵ and more recently by cosmic-ray detectors at PeV energies⁶⁻⁷. There is a consensus that the TeV emission is confined to two short periods in the 4.8-h X-ray modulation cycle⁸, with the stronger period occurring about X-ray phase 0.625. Previous measurements using the Dugway array of four telescopes¹ have indicated that this emission may last for only ~ 10 min. Until 1983, the gross counting rate of the telescope array was insufficient to allow a search for a possible periodicity.

Observations using improved detectors were made in August–October 1983, with Cyg X-3 being continuously tracked for long intervals under a wide range of weather conditions. The best atmospheric conditions were encountered during a 6-h observation made on 1983 September 12, with ideal weather. The time of arrival of each event was recorded with a resolution of 1 μ s and an absolute uncertainty of ~ 0.5 ms. Each event time was adjusted to Ephemeris time at the solar system barycentre using the MIT ephemeris⁹. At 0519 UT the 4.8-h X-ray phase was 0.625. At this phase a count rate excess was noted which lasted for ~ 7 min. The most important feature of this 7-min interval is that it offers, for the first time, a sample of sufficient size and signal strength to make a pulsar period search worthwhile.

We have tested the 450 events contained in the 7-min interval for periodicity over the range 10 ms to 50 s, using the most appropriate test for the power in the fundamental—the Rayleigh test¹⁰. The period with by far the smallest probability of a chance origin was 12.5908 ms, the probability being 4.8×10^{-8} (see Fig. 1a). Allowing for the number of periods tested, the true significance of this periodicity is 3.3×10^{-3} or 3σ . Although in itself not particularly significant, this possible periodicity has the support of further independent evidence.

First, we have considered the possible correlation between counting rate and periodicity within the 7-min interval. If the periodicity is genuine, the onset and decay of the count rate excess should, on average, be mapped by the variation in the fraction of the counts which are periodic. In the null case (that the apparent periodicity is just a random fluctuation) the fraction of counts which are apparently periodic should be independent of the actual number of counts, hence there should be no correlation between these values. As the joint probability of a segment of the 7-min interval having a particular fractional periodicity and also having a particular gross number of counts (given the null hypothesis of no real periodicity) can be factorized, a correlation would provide independent evidence of periodicity¹¹. Although, formally, product moment correlation requires normally distributed samples, in practice a wide variation of sampling distributions is found to be permitted^{12,13}. We find that the strength of the 12.5908-ms periodic component

Fig. 1 *a*, The chance probability for periodicity in the 450 events containing the count rate excess on 1983 September 12, as a function of trial period. *b*, The chance probability of periodicity for the events on 1983 October 2 at precisely the same phase in the 4.8-h cycle as was investigated on 1983 September 12, as a function of trial period.

correlates (at a significance level of 9.5×10^{-4} or 3.1σ) with the count rate in independent 1-min data segments within the 7-min interval. The correlation arises mainly from two of the minutes (which are 3 min apart and are roughly centred in the 7-min interval) during which both the counting rate and the periodic signal are both particularly strong.

Second, we examined other nearby data sets containing precisely the same phase in the 4.8-h period. During August–October 1983, seven other such observations of Cyg X-3 were made. In no case were the climatic conditions stable enough to allow reliable use of the minute-by-minute count rates to unambiguously identify a count rate excess. However, tests for millisecond periodicity at a known period are possible in such data. For one of the seven observations (1983 October 2) exactly 100 4.8-h cycles after the detection on September 12, a periodicity was observed in the 7-min interval at 12.5908 ms, with a chance probability of 4×10^{-4} (see Fig. 1b) (the larger chance probability reflects the lower counting rate due to non-ideal climatic conditions during the October measurements).

The interpretation of this second occurrence of periodicity is complicated by the possible presence of two 19-day periodic effects: a 19.3-day amplitude modulation⁵ of the TeV emission at X-ray phase 0.625 based on our 1981/82 data, and the 18.7 day phase modulation of amplitude ± 3 min in the time of the X-ray minimum found by the COS-B X-ray detector¹⁴ and attributed to apsidal motion. If the 19.3-day amplitude modulation is genuine, and since the excess on September 12 was near a 19.3-day peak, the October 2 observation would be the one expected to show the most significant periodic excess. Because of the 18.7-day phase modulation, the 20-day separation of our two observations may produce up to a minute in phase difference. We note that data in a 7-min interval centred 50 s later than the precise time predicted from the X-ray ephemeris and our previous measurement, show periodicity at 12.5908 ms with a smaller chance probability, that is, 4×10^{-5} .

To be conservative, we have (1) allowed degrees of freedom for all seven observations, ignoring any possible 19.3-day amplitude modulation (although this is noted for future confirmatory observations) and (2) ignored the possible improvement in

Fig. 2 The chance probability of periodicity (12.5908 ms) as a function of phase in the nominal 4.8-h period, for observations on 1982 August 25 and November 14.

chance probability by shifting the time of the 7-min interval to allow for possible apsidal motion. This leads to a chance probability of 2.8×10^{-3} for detecting a 12.5908-ms periodicity on any one of the seven occasions.

Finally, we have demonstrated previously that those events which trigger two separate telescopes spaced 60 m apart (twofold events) have a narrower acceptance angle distribution than is the case for events registered in a single telescope¹⁵. A point source of γ -rays centred in the field of view will consequently have a proportionally greater effect on the rate of cosmic-ray background detected as twofold responses than is the case for single-telescope responses. In the present observation, the fraction of the twofold events showing periodicity was 1.5 times greater than that of the single-telescope events, in accord with our previous experience. However, the restricted sample size gives an uncertainty of ± 0.5 in this value so that, in this case, formal use cannot be made of the increased sensitivity of the two-fold responses.

Although the general periodicity search was terminated at 10 ms because of the possible loss of coherence for shorter periods, periods near integral factors of 12.5908 ms have been searched for in shorter segments of the 7-min interval. No evidence was found to indicate that 12.5908 ms is a multiple of a shorter periodicity.

Our data for 1983 thus provide chance probabilities of: (1) 3.3×10^{-3} (September 12 periodicity allowing for all periods tested); (2) 9.5×10^{-4} (correlated periodicity and count rate on September 12); and (3) 2.8×10^{-3} (periodicity on October 2 at precisely the predicted phase in the 4.8-hr cycle, allowing for non-detection of signals from six other data sets). These three probabilities are derived from independent data or independent tests on the same data and may therefore be combined. The combined probability of 4×10^{-7} is conservative.

To check for possible instrumental effects, off-source data from the same and adjacent nights were analysed similarly and the Rayleigh test probability distributions are found to be those expected by chance, as is the distribution during the 7-min excess, discounting the 12.5908-ms peak. The 12.5908-ms periodicity was detected in each of the four well-separated (100 m) telescopes which were operated and triggered independently, largely excluding the possibility that local pick-up caused the increase in counting rate. Also, more data were available on each event other than the time of arrival (UT). The relative times of triggering of each detector were recorded with 150-ps resolution. For those events which triggered two or more detectors, the correct time separation was observed for Cerenkov light flashes in the field of view. The pulse height in all three of the photomultipliers on each detector was also recorded for each

Fig. 3 Light curve for the TeV γ -ray emission during the 7-min data set at X-ray maximum on 1983 September 12.

event, and the spectrum during the 7-min interval was that expected for Cerenkov flashes. All the anode currents and photoelectron noise trigger rates of the individual photomultipliers were also recorded and were normal during the 7-min interval. Therefore, we believe that the events giving rise to the periodic excess were genuine Cerenkov light flashes in the field of view.

We have examined our 1982 data for instances of similar periodicity. In 1982 the counting rates were considerably lower than in 1983, and we would not expect any significant contribution to the overall chance probability of periodicity from an interpretation of these data. Furthermore, the absolute phase in the 4.8-h orbit of the data to be tested will have uncertainty due to variations arising from possible apsidal motion and from errors in the ephemeris for the 4.8-h period. The uncertainties in the 4.8-h period suggest variations of ~ 5 –10 min in the phase in 1982 relative to that in 1983. We have therefore passed a window of 7 min duration through the data, incrementing the start time by 1-min steps spanning ± 15 min from the nominal phase 0.625. The nominal 4.8-h orbit uses the van der Klis and Bonnet-Bidaud⁸ ephemeris incorporating a period derivative. Each data set was tested for periodicity at 12.5908 ms. There is evidence for periodicity during 2 of the 14 observations (compared with 2 out of 8 in 1983). The strength of the periodicity as a function of the nominal 4.8-h phase on these two occasions is shown in Fig. 2. These two detections concur in the emission being earlier than the nominal phase. There is thus support for 12-ms periodicity from the 1982 data. Our 1981 data were taken in drift-scan mode with detectors of lower counting rate and less precise millisecond timekeeping and thus are less suitable for this analysis.

If the 4.8-h X-ray modulation is due to an orbit, as is generally concluded, the sections of data suggesting periodicity and lasting for 7 min should show some evidence of an orbitally derived period derivative. The periodicity test has been relaxed for a range of values of period derivative between -10^{-8} and $+10^{-8} \text{ s s}^{-1}$. The combined probability for the two positive data sets in 1983 was found to minimize for a small negative derivative: $-1.2 \pm 0.7 \times 10^{-9} \text{ s s}^{-1}$. A similar treatment of the two data sets in 1982 gave a derivative of $-0.6 \pm 0.4 \times 10^{-9} \text{ s s}^{-1}$. These estimates combine to give $-7.5 \pm 3.5 \times 10^{-10} \text{ s s}^{-1}$. This negative value of derivative places the source of the TeV emission, which coincides with the X-ray maximum, in the rear half of the orbit. Because the TeV emission is at X-ray maximum, this result (which is significant only at the 2σ level) conflicts with the two main models for the X-ray modulation—the cocoon model and the stellar wind model. In these models the X-ray emitter is in front of the companion at X-ray maximum. Both models assume the X-ray source is an accreting neutron star or a pulsar and the X-ray modulation is due to variations in the absorption or scattering, and both models require a significant orbital eccentricity. However, the sign of the derivative is consistent with a TeV-emission model¹⁶ and places the source of the very-high

energy ions behind the companion's atmosphere at the time of TeV emission. With the assumptions that TeV γ -ray emission occurs when the pulsar is almost directly behind the companion, and that the orbit is nearly circular (as inferred from the COS-B observations of the 18.7-day X-ray phase modulation), the observed period derivative of $-10^{-9} \text{ s s}^{-1}$ would correspond to an orbital velocity of $\sim 80 \text{ km s}^{-1}$. In this case the Keplerian mass function would be $\sim 0.01 M_{\odot}$.

Recently, two models have been proposed to explain the production of TeV and PeV γ -rays from Cyg X-3: (1) the luminosity is derived from the rotational energy of a rapidly spinning ($\sim 10 \text{ ms}$) neutron star of high magnetic field¹⁶, and (2) acceleration of ions occurs in an accretion disk surrounding a neutron star by the unipolar inductor mechanism¹⁷. Both models require the high-energy ions to interact with the atmosphere of the companion to produce the γ -rays. The light curve for the TeV emission during the 7-min interval on 1983 September 12 (for a period of 12.5908 ms and including the period derivative) is broad (see Fig. 3). The curve for the emission on October 2 is similar, and both curves have the same form as the TeV light curves of other X-ray binaries (Hercules X-1¹⁸; 4U0115¹⁹) and the 6-ms pulsar PSR1953+29²⁰. This is in contrast to the very sharp light curve in the case of an isolated pulsar—the Crab²¹. This suggests that accretion from a pulsar's binary companion plays an important part in the TeV emission.

The TeV γ -ray flux appropriate to this observation is consistent with our previous measurement¹ of $10^{-39} \text{ W m}^{-2} \text{ Hz}^{-1}$. The differential power-law spectral index of ~ 1 implicit in a comparison of this flux with the X-ray flux suggests that TeV γ -rays constitute the majority of the electromagnetic emission from Cyg X-3. The total energy flux, over all wavelengths, has been estimated at $\sim 10^{38} \text{ erg s}^{-1}$; this, together with a pulsar period of 12.5908 ms, would require a spin-down period derivative, given a magnetic field similar to that of the Crab pulsar, of about $10^{-14} \text{ s s}^{-1}$. On the other hand, an accretion-driven low-magnetic-field system may be in equilibrium or may be spinning up. In either case, the change in period expected between the observations in 1983 and those in 1982 would be $< 0.3 \mu\text{s}$. Our sampling uncertainty in period is about the same, precluding any measurement of a secular period change until a precise orbit has been determined.

Thus, we have prima facie evidence from our 1983 data, at a chance probability of 4×10^{-7} , that the excess counts of 1,000-GeV γ -rays noted from Cyg X-3 at orbital phase 0.625 in the 4.8-h X-ray cycle are all periodic, with a period in the orbit in 1983 September/October of $12.5908 \pm 0.0003 \text{ ms}$. Other qualitative evidence from observations in 1983 and 1982 supports this suggestion. However, further observations of Cyg X-3 are required to confirm the existence of this periodicity. Note that for all other wavelength bands where Cyg X-3 has been detected, current models would predict that such a millisecond pulsar periodicity would be greatly attenuated due to dispersion or scattering in the cocoon or dense stellar wind surrounding the companion. However, rapid quasi-periodic oscillations reported recently²² from GX5-1 have been interpreted^{22,23} as beating between the period of a fast pulsar and the orbital period of the inner edge of the accretion disk. Such indirect effects of a 12.59-ms pulsar may be detectable, or may be involved in the longer-period quasi-periodic oscillations already detected from Cyg X-3 (ref. 24).

We thank SERC for funding this work and for the provision of studentships (I.W.K., M.W., J.C.D. and P.M.C.). The Commander and staff of Dugway Proving Ground are thanked for their help and support.

Optical polarization observations of circumsolar dust during the 1983 solar eclipse

Syuzo Isobe*, Tomohiro Hirayama*, Naoshi Baba† & Noriaki Miura†

* Tokyo Astronomical Observatory, University of Tokyo, Mitaka, Tokyo 181, Japan

† Faculty of Engineering, Hokkaido University, Sapporo, Hokkaido 060, Japan

It is very difficult to make optical observations from the Earth where the angular distance from the Sun is greater than $3 R_{\odot}$ (where R_{\odot} is the angular radius of the Sun) because of the large and uncertain correction for sky radiation. To overcome these difficulties, we have now made optical polarization observations at four wavelengths (5,330 Å, 5,970 Å, 7,200 Å, 8,015 Å) for the outer solar corona at an altitude of 30 km, using a balloon-borne silicon-intensified (SIT) TV camera during the total solar eclipse on 11 June 1983 in Indonesia. As reported here, a polarization excess at an elongation between 4 and $5 R_{\odot}$ (1° and 1.25°) from the Sun in the ecliptic plane was observed at a wavelength of 8,015 Å on the two-dimensional frame. This is interpreted as an enhancement of dust grains distributed in a ring around the Sun approximately in the ecliptic plane.

Infrared excesses have been observed¹⁻⁵ at the elongation around 4 and $10 R_{\odot}$ which have confirmed the existence of a

R is the angular distance from the Sun in units of R_{\odot} . θ is the angle of radial line from the Sun to the ecliptic. $\theta = 0^{\circ}$ is on the ecliptic and $\theta = 10^{\circ}$ in the north is on the solar equator. At $R = 3.6 R_{\odot}$, data are probably affected by the occulting disk.

Fig. 1 An intensity contour map at a wavelength of 8,015 Å. The small circle and the large ellipse are the positions of the Sun and the occulting disk, respectively. The two areas suffering ghost images are hatched. The contour unit is arbitrary. The field-of-view is $5^\circ \times 5^\circ$ corresponding to $20 \times 20 R_\odot$. North is down and west is left.

Fig. 2 A contour map of polarization degree in a field of $5^\circ \times 5^\circ$. Contour unit is 5%. The ecliptic plane and solar equator are shown by thick and thin lines, respectively. North is down and west is left. The length and direction of each short line denote degree of polarization and direction of electrical vector, respectively. Note that there is some effect of the ghost images in the areas shown in Fig. 1.

dust-free zone inside the solar distance (radial distance from the Sun) at about $4 r_\odot$ (r_\odot is the linear radius of the Sun), and indicates that there is a ring-shaped enhancement in the density of dust grains along the outer edge of this zone. To observe these areas, we used an optical telescope with a field of $5^\circ \times 5^\circ$ ($20 \times 20 R_\odot$) centred almost on the Sun. Because our SIT TV camera has 256×256 pixels, the observed resolution is $0.08 R_\odot$. Apart from the introduction of a small shift of the Sun (10 arc min to the south-west; upper left in Fig. 1) from the centre of the occulting disk to eliminate bright light from the inner corona, the observations were successful. Unfortunately, the shift had severe saturation effects on the observations at 5,330 Å, 5,970 Å and 7,200 Å, and therefore only the observational data at 8,015 Å are presented here. All the data, including those at the other wavelengths, will be published elsewhere^{6,7}.

During the 140 s of the observation, we rotated two wheels: the filter wheel was kept fixed for 15 s (in each filter) while the polarizer wheel was rotated to each of the eight positions, remaining in each position for 1.8 s. We thus have two complete sets of polarization observations at the four wavelengths. All observational data were recorded by a video recorder on-board the balloon. After recovery of the tape, all video data were transferred to digital data using a computer with a 16-bit double-frame memory. To control for the non-uniformity of the detector sensitivity of the SIT TV cameras and the instrumental polarization created by our telescope system, artificial uniform unpolarized light was measured. After correction, the error of polarization at each point of the detector was estimated to be $\pm 1\%$. Although the asymmetrical position of the Sun in the TV frame made two ghost images (see Fig. 1), there was no effect on the other areas in the field.

Figure 2 shows a contour map of the degree of polarization, where the length and direction of each line denote the degree of polarization and the direction of the electrical vector, respectively. The polarization vector should be perpendicular to the radial direction from the Sun, because coronal light is scattered by coronal electrons (K corona) and interplanetary dust (F corona). Most vectors shown in Fig. 2 satisfied this condition. The numerical values of the degrees of polarization in the areas of interest are shown in Table 1 and indicate a smooth variation of polarization between successive points. It has been difficult to separate the two components of the F and K corona in the observed intensity, for the only way to separate them is to

observe the depth of Fraunhofer lines in the spectrum of the corona and to compare them with the depth in the solar spectrum⁸. We have observed the total intensities of the combined F and K coronal components and so could obtain no information on their relative proportions. Van de Hulst⁹ collected data on the F and K coronal components between 1 and $10 R_\odot$ and showed that the K component is brighter than the F component at an elongation of $< 2 R_\odot$, but decreases to $< 20\%$ of the F component beyond an elongation of $3.5 R_\odot$ except for the area of the coronal stream. Figure 2 shows clearly an area with a high degree of polarization which corresponds to a coronal stream.

We have compared our polarization distribution in the ecliptic plane with other results. Blackwell and Petford⁸ observed the outer corona and obtained the intensity and polarization of the F and K components at an elongation greater than $5 R_\odot$. Following their results, the degree of polarization of total light for the F and K components is $< 8\%$. During the solar eclipse on 5 February 1962, Saito and Hata¹⁰ made an observation of the polarization at 6,200 Å and showed that the degree of polarization decreases between 1.2 and $3.0 R_\odot$ in elongation and that the extrapolated value at an elongation of $5 R_\odot$ is $< 10\%$. Our results show $\sim 17\%$ polarization at an elongation of between 4 and $5 R_\odot$ (see Fig. 3). It is not clear why the previous results did not show high polarization at elongations between 4 and $5 R_\odot$, but we think that photographic observations of polarization such as those of Saito and Hata have a low signal-to-noise ratio at the elongation considered and that photoelectric observations of polarization cover only a small coronal area in each limited observational period during the solar eclipse. Unfortunately, Blackwell and Petford's extensive observations were carried out at large elongations ($5\text{--}16 R_\odot$). Our observations were carried out using a SIT TV camera with as high an accuracy as is obtained with photoelectric observations and, using a two-dimensional frame for the photographic observations, show an area of high polarization (see Figs 2, 3).

If there is an enhancement in the density of dust grains around $4 r_\odot$ as suggested by the infrared observation, the enhanced grains located between 4 and $5 r_\odot$ on the line-of-sight, at an elongation between 4 and $5 R_\odot$, scatter the solar light with a scattering angle of around 90° . The scattered light is polarized by 0–60% depending on the refractive index and radius of dust grains and on the wavelength of the light^{11,12}. Therefore, one

Fig. 3 Degree of polarization depending on the elongation in the ecliptic plane. Thin solid (1) and thick dashed (2) lines are those observed by Saito and Hata¹⁰ in the east and west directions respectively. Thin dashed line (3) is an extrapolation of thin solid line. Dashed-dotted line (4) shows the results of Blackwell and Petford⁸. Thick solid line (5) is our result in the west direction which shows a high degree of polarization at the elongation between 4 and 5 R_{\odot} . There is a jump of polarization from 0 to 15% at the elongation of 3.8 R_{\odot} corresponding to the cutoff point of the occulting disk, but the peak of polarization at 4.0 R_{\odot} is real. The observational error is 1% at the inner region.

can expect a high value for polarization at an elongation between 4 and 5 R_{\odot} in the ecliptic plane as a result of dust grains that have a scattering angle of $\sim 90^{\circ}$. Because there is no enhancement of polarization in the direction perpendicular to the ecliptic plane in Fig. 2, the region with the highest number density of dust grains does not extend far from the ecliptic plane.

We conclude that there is an enhancement of the degree of optical polarization at an elongation between 4 and 5 R_{\odot} which suggests that the number of dust grains distributed in a ring around the Sun increases approximately at the ecliptic plane.

This work is part of a joint project of the Tokyo Astronomical Observatory, Institute of Space and Astronautical Sciences, University of Kyoto, and the Indonesian Aeronautical and Space Administration. The project was supported by funds from the Ministry of Education, Science and Culture. We thank Mr S. Miyaki (Hamamatsu Photonics K. K.) for his support.

Decay of the cometary bow shock

M. K. Wallis* & M. Dryer†

* Department of Applied Maths and Astronomy, University College Cardiff, Cardiff CF1 1XL, UK

† NOAA Space Environment Laboratory, Boulder, Colorado 80302, USA

Cooling processes will weaken the bow shock that is expected to form when the solar wind plasma encounters a gassy comet. As the supersonic wind penetrates the comet's outer coma, accreting freshly ionized cometary atoms and molecules, it needs a shock to adjust to the inner subsonic conditions. The cometary ions, implanted in the plasma stream, are accelerated by the associated fields and take up much of the decrease in streaming energy. The

subsonic flow in comets is distinguished by strong cooling, effected primarily through ion-molecule reactions between the energetic implanted ions and the neutral gas coma. We argue here that such cooling can cause complete decay of the shock's flanks, as probed by the ICE (International Cometary Explorer) spacecraft at comet Giacobini-Zinner.

To the on-rushing solar wind, the extensive and rarefied cometary coma presents a very different obstacle from a planetary magnetosphere, or even a planetary exosphere such as Venus. The solar wind plasma penetrates freely through the outer coma, except that associated electric and magnetic fields couple it to occasional freshly ionized cometary atoms and molecules. These implanted cometary ions have commonly been viewed as 'picked up' in the plasma flow, their bulk effect being modelled as sources of mass m , momentum S and energy E added to the gas-dynamic equations for the flow¹. The sources combine to constitute the generalized drag^{2,3}

$$D = \frac{1}{2}(\gamma + 1)m - \gamma S/u + \frac{1}{2}(\gamma - 1)E/u^2 \quad (1)$$

in a flow at speed u , specific heat ratio γ . Evidently, mass-accreting ($m > 0$) and frictional ($S < 0$) contributions to D are offset by cooling ($E < 0$). This drag coefficient D enters the 'throat' equation, crucial for investigating transonic gas-dynamic flows⁴: for a streamtube of cross-sectional area A and length z ,

$$(1 - M^2)du/u = M^2 D dz/\rho u - dA/A \quad (2)$$

where $M = \sqrt{\rho u^2/\gamma p}$ is the Mach number, ρ the density and p the pressure. While flows with 'mass-loading' alone with D everywhere positive have attracted much attention, the presence of an inner region with negative D (see ref. 5) is emphasized here.

Solutions investigated in the case $S = 0$, $E = 0$, have subsonic flow ahead of the nucleus that is close to incompressible and possesses a weak bow shock^{5,6}. The shock is about Mach-2 at the nose and is very blunt, crossing $z = 0$ at some 2.5-3 times the stand-off distance; its Mach number increases towards the flanks⁷. Its strength is sufficient to diverge the flow ahead of any impenetrable inner region (magnetosphere/ionosphere), which would be smaller in size by an order-of-magnitude (for computational purposes, Biermann *et al.*⁷ assumed an artificially large inner cylinder, while Lipatov's^{8,9} magnetohydrodynamic calculation has an inner magnetic sheath conditioned by large gyroradius effects).

However, momentum and energy losses are likely to be very significant. Implanted cometary ions, entrained by electromagnetic fields associated with the plasma flow, gain much of the deceleration energy², having 40% of the total pressure behind the shock in the transverse field situation calculated by Galeev *et al.*¹⁰. When they undergo charge-exchanging reactions, such as

most of their energy and momentum is lost with the neutralized particle. This is sufficient to drive D [equation (1)] negative at low enough Mach number². When the ions are highly suprathermal, D can go negative at Mach numbers little less than unity¹⁰, as in a Venus interaction model².

An additional loss process for the energetic cometaries arises because they drift across the bulk plasma flow threaded by a magnetic field that is draped around the comet on the large scale^{11,12}. In such a field structure, fresh ions originating in the sunward coma generally diverge from the symmetry axis¹². Their mean effect is additional cooling and a loss of momentum that supplement the losses through charge exchange. The situation differs from that investigated by spacecraft at Venus or in the artificial AMPTE (Active Magnetospheric Particle Tracer Explorers) comet, where the obstacle and boundary layer scales were smaller than gyroradii of new ions. In such cases (see ref. 13), charge separation results in sheaths and streaming instabilities with intense, short-wavelength electric fields.

In the presence of strong cooling, Galeev *et al.*¹⁰ proposed a solution with re-accelerated flow and excluded any stagnation region. But that depends on the assumption of incompressibility:

Fig. 1 Plasma flow through the coma under strong cooling. Schematic streamlines and expansion/compression wave patterns are sketched using the $M=1$, $M=2$ lines displaced upstream from those computed for mass-accreting flow (dotted lines).

$uA = \text{constant}$ which, combined with equation (2), requires $du = -Ddz/\rho > 0$. We choose the alternative behaviour, whereby streamtubes tend to reconverge due to low inner pressure: then $dA \approx 0$, which allows $du < 0$ [for $Ddz < 0$] continuing into the stagnating flow.

In this case, the flow pattern would be as sketched in Fig. 1. There is a small ionosphere plus tail of relatively cool plasma in the interior, with a stagnation region ahead but converging streamlines farther out. The sonic line is displaced sunwards from that computed in mass-source models⁷⁻⁹ and Mach numbers are higher behind the cooled coma, as indicated by the $M = \sqrt{(\rho u^2/\gamma p)} = 2$ line. The intermediate region of the coma acts more like a 'sink' than an ion 'source' due to its cooling power. The negative D acts to accelerate the supersonic flow². Qualitatively, we use gas-dynamic arguments^{4,14} to sketch patterns of expansion waves emitted from convex arcs of streamlines. Such expansion waves propagate out at the angle $\arcsin(1/M)$ to the flow and on reaching the flanks of the bow shock weaken it. They also bend the bow shock more sharply downstream. If the flow close to the ionosheath is primarily converging (as estimates indicate), the total weakening will be sufficient to cause complete decay of the shock's limbs, leaving Mach waves or propagating Alfvén waves. Of the two cases we discussed earlier¹⁵, the heliosphere with cooled, convergent wake is closest to the present case. The concave downstream streamlines emit compression waves, but the tailside coma provides decreasing friction ($S \uparrow 0$) like a supersonic diffuser, giving increasing Mach number in the emergent flow: the waves may, therefore, diverge as in Fig. 1, rather than converge to the classical tail shock. The innermost ionospheric tail can still, in principle, have the complex wave pattern of a supersonic jet¹⁵.

The gas-dynamic description of equation (2) needs modification to describe the magnetized flow properly. However, the differences are small when the field is weak, as is the case for energy density some 2–5% of the flow energy. Then, the magnetic field behaves primarily as though convected outside 0.1 times the shock scale¹¹. There is a magnetic contribution to the pressure with an effective γ of 2, which limits the potential compression effected by cooling. In addition, Maxwell stresses transfer some momentum from the solar plasma that is convecting the outer parts of draped field lines, to the cometary plasma that's dragging back the inner parts. The net result is extra acceleration of the sheath around the tail wake and ionosphere (Fig. 1) compared with the gas-dynamical case, but there is no qualitative difference

compared with our flow pattern.

The ICE spacecraft is targeted to fly through the wake of comet Giacobini-Zinner at $>10,000$ km downstream, that is at >0.3 times the shock stand-off scale¹⁶. It is hoped that the location of the shock flanks and the size of density and field jumps will reveal the nature of the shock and how far the solar wind "is deflected around or mingles with cometary plasma"¹⁷. We suggest, however, that interpretations will not be straightforward. The bow-shock flanks will be less widely flared and weaker than those given by the mass-source model and may be fully decayed. The main signature of the solar wind interaction will be the presence of energetic cometary 'pick-up' ions, whose places of origin will be complicated by significant drifts relative to solar protons.

The ICE spacecraft flew through the comet tail on 10 September at 8,000 km downstream. Initial results¹⁸ show an ionospheric tail and energetic ions over an extensive region but no bow shock, in agreement with our present prediction.

M.K.W. is grateful for hospitality at NOAA where this study originated.

Underwater noise caused by precipitation

Joseph A. Scrimger

Jasco Research Ltd, Marine Technology Centre,
9865 W. Saanich Road, R.R.2, Sidney, British Columbia,
Canada V8L 3S1

The characteristics of underwater noise in the ocean generated by precipitation are important to weather forecasters and oceanographers because they permit the detection and measurement of rain over the oceans by remote (buoyed or bottom-mounted) acoustic sensors. We have recently observed the characteristics of the underwater noise generated by rain, hail and snow. The spectrum of rain noise, for wind speeds below 1.5 m s^{-1} , shows a peak at 13.5 kHz with a sharp cutoff on the low-frequency side and a gradual fall-off (7 dB per octave) on the high-frequency side. Stronger winds smear the peak. Hail spectra show a peak at 3.0 kHz with a gradual (roughly 11 dB per octave) fall-off on both sides. The spectrum of snow noise is unique. Our instrumentation permitted the measurement of the drop (or stone) size distributions in the precipitation. These findings will enhance the art of remote acoustic sensing in oceanography.

Traditionally, the study of undersea acoustic noise has remained the province of the sonar designer and his co-workers because it sets limits on the detection capabilities of sonar equipment. The characteristics of such noise have been determined by many workers^{1–4} and the primary causes have been attributed to wind, shipping and, in shallow water, to biological organisms

Fig. 1 Underwater noise spectra of rain (a-c), hail and snow for wind speeds $> 1.5 \text{ m s}^{-1}$. Spectrum level is expressed in dB relative to $1 \mu\text{Pa}^2 \text{ Hz}^{-1}$. Rain rates: a, 1.1 mm h^{-1} ; b, 0.29 mm h^{-1} ; c, 0.13 mm h^{-1} . Wind speeds: a, 2.7 m s^{-1} ; b, 2.7 m s^{-1} ; c, 2.23 m s^{-1} .

In recent years, 'the inverse problem' has been in vogue. Here the underwater noise becomes the signal, and measurement of this quantity in deep water appears to constitute a valid measurement of wind speed above the water surface. Measurements of wind speed and undersea noise level exhibit a high correlation, although relatively short-duration peaks in the noise records were attributed to rain by Shaw *et al.*⁵, who suggested the use of two or more observation frequencies to distinguish between wind- and rain-induced noise. Lemon *et al.*⁶ showed that undersea noise measured in three frequency bands centred at 4.3, 8.0 and 14.5 kHz on a continental shelf was readily inverted, through a simple logarithmic relationship, to wind speed within $\pm 1.5 \text{ m s}^{-1}$, for wind speeds in the range $0-12 \text{ m s}^{-1}$, and also obtained estimates, using Franz's⁷ data, of rainfall amounts which agreed within a factor of 2 with those obtained at nearby shore stations.

The undersea noise induced by precipitation has received little attention. Franz⁷ developed a theoretical expression for the spectrum of rain noise based on measurements of the underwater noise produced in a tank by sprays of droplets from a form of shower head. Heindsmann *et al.*⁸ reported some observations of undersea noise intensity resulting from rain showers in Long Island Sound, while Bom⁹ obtained spectra of underwater rain noise in the 1,200–9,600-Hz frequency band in Sarzana Lake in northern Italy. Nystuen¹⁰ has reported on some broadband measurements made in Clinton Lake.

During the winter of 1984–85, we made selected observations of underwater noise produced by carefully monitored precipitation in a roughly 4-km² arm at the eastern end of Cowichan Lake, South Vancouver Island, British Columbia, Canada ($48^\circ 48' 15'' \text{ N}$, $124^\circ 10' 12'' \text{ W}$). The forms of precipitation observed were rain, hail and snow, observations of the latter two forms being by chance rather than from experimental intent.

The hydrophone (an ITC 8084A having a near-spherical spatial response and a quasi-flat frequency response over the

Fig. 2 Underwater noise spectra of rain for wind speeds $< 1.5 \text{ m s}^{-1}$. Spectrum level is expressed in dB relative to $1 \mu\text{Pa}^2 \text{ Hz}^{-1}$. Rain rates: d, 0.7 mm h^{-1} ; e, 0.2 mm h^{-1} ; f, 0.11 mm h^{-1} . Wind speeds: d, 0.76 m s^{-1} ; e, 0.59 m s^{-1} ; f, 0.45 m s^{-1} .

range 1–50 kHz) was mounted 0.7 m from the lake bottom in 35 m of water some 300 m from shore and its signal was carried by cable, after pre-amplification, to a recording facility ashore. After further amplification and improvement in the frequency response (flat $\pm 0.5 \text{ dB}$) over the frequency range, the signal was fed to an HP 3580A spectrum analyser using a 300-Hz-wide swept filter, which provided adequate resolution for the form of spectra observed and presented here. Wind speed and rain rate measurements were made ashore on a flat, bare tract of land virtually co-planar with the water surface, using conventional Government of Canada equipment and a Distromet RD69 distrometer.

Figure 1 shows underwater noise spectra due to hail, rain (a-c) and snow. The three rain noise spectra, corresponding to the rain rates given in Table 1, are typical of the bulk of the spectra for light rain which were collected. Figure 1 illustrates the characteristics of the rain spectra for wind speeds of $\sim 2.6 \text{ m s}^{-1}$ through a constant fall-off in sound level of about 7.0 dB per octave for frequencies increasing above 18 kHz, a rounded peak in the frequency interval 12–18 kHz and a rapid fall-off in sound level of roughly 45 dB per octave for frequencies decreasing below 12 kHz. Below 8 kHz, these spectra show more gradual slopes of $\sim 4 \text{ dB}$ reduction in level for each octave increase in frequency.

The noise spectrum produced by hail is quite different from that of the rain noise, showing a single broad peak centred at 3 kHz, with a fall-off of 10- and 12-dB per octave on the high- and low-frequency sides of the peak respectively. As one might expect, the noise spectrum due to snow is of low level, and is characterized by a gradual increase of the order of 3–5 dB per octave as the frequency increases.

Figure 2 shows a set of rain noise spectra taken in calm conditions. In contrast to those shown in Fig. 1, these spectra exhibit a very sharp cutoff at 13.5 kHz. The fall-off on the high-frequency side of the peak is between 6.5 and 10 dB per octave, essentially the same as those of the rain noise spectra taken with wind speeds of 2.6 m s^{-1} , while on the low-frequency side the spectral slope is 55–65 dB per octave. The low-frequency slope ($< 5 \text{ kHz}$) is 3 dB per octave, with the level decreasing

Table 1 Drop size distributions in terms of the number of raindrops (or hailstones) in a given diameter interval falling on 1 m^2 of the surface per s

Spectrum	Drop diameter interval (mm)															Total no. of drops ($\text{m}^{-2} \text{ s}^{-1}$)	Mean rain rate (mm h^{-1})	Kinetic energy (dB) re spectrum f

Fig. 3 Comparison of rain noise spectral samples due to Franz (—), Bom (—), Nystuen (---) and Scrimger (wind $< 1.5 \text{ m s}^{-1}$ (+—+), wind $> 1.5 \text{ m s}^{-1}$ (—)). Spectrum level is expressed in dB relative to $1 \mu\text{Pa}^2 \text{ Hz}^{-1}$. Numbers adjacent to curves are rain rate in mm h^{-1} .

with increasing frequency. Figure 3 compares our results with those reported by other workers.

The use of a distrometer permitted the determination of the drop size distributions in the rain producing the acoustic noise samples. These are given in Table 1, which shows the number of drops in a given drop-size interval, expressed in terms of the drop diameter, falling on 1 m^2 of the surface per s. Also given is the rain rate derived from the drop counts and the power input per m^2 at the surface due to the kinetic energy of the drops, expressed in dB, referred to the power associated with the rain noise of spectrum f . The latter was chosen as it was obtained from the lightest rainfall of the samples considered. The distrometer samples were 30 s long, so that three contiguous samples were added to correspond to a single 90-s sample obtained in near coincidence with the 100 s needed to produce the acoustic spectrum.

These data are remarkable for the abrupt fall-off in level of the rain noise spectra below 13 kHz and particularly for the sharp contrast in form between the spectra of the rain noise taken in winds of speeds $< 1.5 \text{ m s}^{-1}$ compared with those taken in winds of greater speed. In the 17 spectra obtained in winds of speeds below 1.5 m s^{-1} , which might well be considered 'pure' rain noise spectra, the peak occurs at 13.5 kHz within a few hundred hertz and the cutoff on the low-frequency side of the peak is extremely sharp, dropping the spectrum level over 15 dB in a 2-kHz frequency interval. Evidently, the wind, as it increases in speed above 1.5 m s^{-1} , affects the noise generation mechanism in such a way that the 13.5-kHz peak is rounded off and extended over several kHz and the slope on the low-frequency side of the cutoff is diminished. The hail spectrum above 15 kHz is essentially the same as the rain spectra but it does not exhibit the cutoff near 13.5 kHz, and peaks at 3.0 kHz. Considering the different properties of hail and rain—the rigidity of the hail and the fluidity and surface tension of the rain—the simplicity of the hail spectrum compared with that of the rain is not surprising. Also, *a priori*, the negative slopes of the respective spectra towards high frequencies are consistent with the concept that the higher-frequency energy in the noise is generated by the smaller drops (or stones) and that these input less energy (both kinetic and, in the case of rain, potential) at the water surface.

The noise spectrum of falling snow is unique in that it increases uniformly at 3 dB per octave as frequency increases over its entire range. As the kinetic energy of the falling snow is negligible compared with hail or rain, the noise must arise from a process associated with the melting of the snow.

I thank Mr Don Evans who designed the instrumentation for this experiment and assisted with the measurements and Messrs Wayman Yee, Vance Loiselle and Malcolm Scrimger who were involved in the equipment design and construction and also the data gathering. The work was supported by several agencies of

the Government of Canada: Department of Supply and Services, Department of National Defence, Atmospheric Environment Service and Institute of Ocean Sciences.

Polymerization of silicate anions in solutions at low concentrations

Robustiano Alvarez & Donald L. Sparks

Department of Plant Science, University of Delaware, Newark, Delaware 19717-1303, USA

Adsorption of tetrahedral-forming ions, such as silicates and phosphates, is considered to be the main cause of retention of these anions on the surfaces of hydrated Al- and Fe-oxides. The importance of this retention in natural and man-caused phenomena has been the subject of many investigations. When adsorption studies are conducted, the role of the surface and the charges developed on it by the potentially determining ions tend to be emphasized, while the nature of the sorbate is rarely considered or investigated. Nevertheless, the excluded or equilibrium solution is the seminal source of information in the formulation of adsorption mechanisms or models. The ionic species present in the equilibrium solution are practically always taken for granted, that is, from data previously published. They are thought to be a simple function of solution pH, without further analysis of ionic speciation changes that occur during the sorption process. Here, we provide direct experimental evidence, using an advanced and sensitive spectroscopic technique, laser Raman spectroscopy (LRS), that aqueous equilibrium silicate solutions at low concentrations contain polymeric and/or other anionic complexes and not just monomeric species. These low concentrations are similar to those used in most previous sorption experiments on Fe- and Al-sesquioxides and on tropical acidic soils. Our findings clearly indicate that any mechanisms and models that are proposed to describe anion sorption on sesquioxides should consider that silicates, and probably some other tetrahedral-forming anions, are not present in solution solely as monomeric ionic species as most investigators have assumed^{1–11}. Irregularities in fitting experimental data to models previously reported prompted this research^{2–4,6,12}.

We determined that a spectrum of Na- or Ca-silicate could be obtained at very low Si concentrations and that the 'fingerprint' approach (Fig. 1) is applicable to the spectra obtained because they have lines distinctly placed, well separated, and of adequate intensity to determine the frequencies at which the peaks or bands occur. The published Raman spectra of Na silicates in solution were determined from Si solutions of concentrations 200–1,000 times larger than the solutions used in this study^{13–16}. No laser Raman (LR) spectra of Ca-silicates in solution have been published.

The spectrum of a Na-silicate solution at a Si concentration of $75 \mu\text{g cm}^{-3}$ is presented in Fig. 1. Numerous precautions were taken to exclude CO_2 from the alkaline solutions. Air-tight plastic bottles were used to store the silicate solution and all of the samples were freshly prepared just before the experiments with degassed water. The solution pHs were measured with a combination electrode immersed in a sealed plastic container to restrict any CO_2 contamination. Unless otherwise stated, all the solutions examined were adjusted to pH 10 since this pH is close to the reported pK of monosilicic acid, that is 9.5 (refs

Fig. 1 Comparison of spectra of Na_2SiO_3 solutions reported by different authors. *a*, Raman spectrum as reported by Fortnum and Edwards¹³. 1, NaH_2PO_4 , 4 M solution (used as silicate analogue); 2, Na_2SiO_3 , 2.5 M. *b*, Laser Raman spectrum of Na_2SiO_3 1.5 M as reported by Freund^{14,15}. *c*, Laser Raman spectrum of Na_2SiO_3 (multipass device) ($\text{Si} = 75 \mu\text{g per g} \approx 0.003 \text{ M}$).

7–9). This pK_a is a crucial component of the conclusions of many previous investigations. As a basis for comparison, Raman spectra of 1.5 and 2.5 M silicate solutions previously reported^{13–15} are also shown. The remarkable intensity of the Raman lines for the low Si concentration solution is attributed to the enhancement of the signal due to the multipass device used in the studies. A very satisfactory spectrum may also be obtained with Si concentrations as low as $30 \mu\text{g Si cm}^{-3}$. More details of the methodology and the analogue structures suitable for these analyses will be published elsewhere.

Consideration of the position and number of the Raman shifts in the $400\text{--}500 \text{ cm}^{-1}$, 600 cm^{-1} , 785 cm^{-1} , and at the ≈ 900 and $1,050 \text{ cm}^{-1}$ regions agree fairly well. The slight displacement in the 900 and $1,000 \text{ cm}^{-1}$ regions may be due to pH differences. Solutions that are 1.5 or 2.5 M obviously have much higher pHs (> 12) than the $25\text{--}75 \mu\text{g cm}^{-3}$ working range of our Si solutions.

Calcium as well as Na salts are frequently supporting electrolytes in sorption studies, and soluble silicates occur at low concentrations in the soil solution, and in numerous other aqueous environments. When we examined solutions of low Si concentrations, 'anomalies' led to the suspicion that silicate species other than monomers were present. The indications of silicate polymerization or the formation of complexes other than monomeric silicates or silicic acid are reflected in the following LR spectral characteristics: (1) the band at $1,070\text{--}1,090 \text{ cm}^{-1}$ is considered to indicate the presence of a dimer (Si–O–Si band)^{13–15,17} or Si polymers^{13–16,17–20}; (2) changes in the band features, that is, splitting and/or broadening of peaks, shifts of the band frequencies to higher values, and changes of intensity (band height). The lines at $\approx 780 \text{ cm}^{-1}$ are especially sensitive to these changes^{14,15,17–19,21,22}.

The increase in polymerization of the silicate solution is reflected qualitatively by an increase in the intensity of the Raman lines at 780 and $1,070 \text{ cm}^{-1}$ (Fig. 2) in spectrum *b* compared with spectrum *a*. With increasing Si concentration, polymerization of Si rapidly occurs as shown by the development of the peak at $1,070 \text{ cm}^{-1}$ (refs 15, 16, 19–22).

Using times and ionic environments comparable to most other previous sorption studies^{1–6,12}, we determined that a silicate solution of low concentration is not only in monomeric form. Fresh monosilicic acid solutions ($75 \mu\text{g cm}^{-3}$) were prepared using the H-resin method⁸ and brought to pH 10 with NaOH and examined immediately by LRS (Fig. 3). Spectra were run at 15-min intervals and when the solution 'aged' at 3 h, distinct changes in the spectrum as appears in Fig. 3 inset *b* were clearly noticed.

Fig. 2 Laser Raman spectra of aqueous solutions of Na_2SiO_3 with varying concentration. The increase in polymerization in graph *B* is reflected by an increment in the band $= 1,070 \text{ cm}^{-1}$, which corresponds to a silicate dimer (Si–O–Si band) or higher polymer. *a*, Na_2SiO_3 solution at $75 \mu\text{g cm}^{-3}$; *b*, Na_2SiO_3 solution at $100 \mu\text{g cm}^{-3}$.

Fig. 3 Laser Raman spectra of Si-solutions at a Si concentration of $75 \mu\text{g per g}$. Ca(OH)_2 or Na(OH) were added to reach a $\text{pH} = 10$. This pH was selected because between $\text{pH } 8.5$ and 10.5 'maximum adsorption' or 'adsorption envelopes' are reported to occur. *A*, A freshly prepared solution of monosilicic acid and Ca(OH)_2 . *B*, Solution *A* examined after 'ageing' for 3 h after exposure to the laser beam. *C*, Solution *A* examined after ageing for 3 h with no previous exposure to the laser beam. No differences between *B* and *C* were detected, therefore the Si-solution was not polymerized by photocatalysis. Inset: *a*, A freshly prepared solution of monosilicic acid and NaOH. *b*, Solution *a* after ageing for 3 h. The $\approx 782 \text{ cm}^{-1}$ peak broadens, splits and shifts frequency as a sign of polymerization. The labelling of the axes are as in *A*.

The 782 cm^{-1} frequency observed (Fig. 3, insets *a* and *b*) was taken as a reference and it was shown from experimental evidence^{17,22} that the ≈ 780 peak is perturbed when Si polymerizes. This is evident because inspection of the spectra revealed three very distinct alterations of the aged solution in comparison with that at 'zero-time', (Fig. 3, insets *a* and *b*): (1) the band width broadened to twice the value at 'zero-time'; (2) the intensity (band height) decreased nearly 50%; (3) the frequency was displaced from 782 to 803 cm^{-1} . Effects of photocatalysis, due to the laser beam, on the rate of polymerization were ruled out by additional experiments in which Ca was the complementary cation (Fig. 3, *A*, *B*, *C*). Although not shown, a sample of $30 \mu\text{g cm}^{-3}$ Si was examined in similar conditions and even at

this concentration, variations of the 782 cm^{-1} peak occurred 3 h after sample preparation.

The present results are simply a predictable extension of proven facts which explain polymerization, anion bridging and/or gelation of inorganic polymers from solutions at higher concentration than in our studies^{8,9,21,23-28}. They indicate that it is difficult to define a boundary Si concentration, high or low, where silicate monomers are the sole species, which has been the repeated assumption in many previous investigations. Our results confirm that the formation of at least a silicate dimer, at pH 10, predicted from theoretical and experimental reported data^{23,28} occurs at any silicate concentration (in fact, 35% as silicate-dimer, Iler, unpublished data). Even at low concentra-

tions and after a short period of time, a substantial part of the silicate solution is non-monomeric. Moreover, the widely accepted concept that maximum adsorption of silicate on sesquioxides occurs at the $pK_a = \text{pH}$ of monosilicic acid^{1-6,12} without consideration that polymeric species exist has led to incorrect explanations and non-fitted models for those 'adsorption' systems. At $\text{pH} = pK_a$ the conditions are optimal for polymerization to occur^{25,26}. Indeed, our statements do not proscribe sorption of silicates on various sesquioxides in nature and in the laboratory^{1-6,12,22}. Work is in preparation which explains polymerization mechanisms at low concentration, and the possible configurations of dimers and polymeric species, based on evidence from spectroscopy and complementary techniques.

Laboratory models for aromatization and isomerization of hydrocarbons in sedimentary basins

G. D. Abbott, C. A. Lewis & J. R. Maxwell

Organic Geochemistry Unit, University of Bristol, School of Chemistry, Cantock's Close, Bristol BS8 1TS, UK

With increasing depth in the Earth's crust, changes take place in the sedimentary distributions of aromatic steroid hydrocarbons and of stereoisomers of certain types of alkanes^{1,2}. The changes occur before and during the early stages of hydrocarbon generation and have been interpreted as resulting from aromatization and configurational isomerization reactions respectively³. We have now brought about an aromatization reaction and an isomerization reaction in the laboratory under free radical conditions, sulphur being chosen as a convenient source of radicals, and have extracted rate constants from the absolute concentration-time functions of the organic substrates. The activation energies and pre-exponential factors were then deduced from the temperature dependence of the rate coefficients. The values of these activation parameters show that, in the laboratory, the aromatization is more temperature dependent than the isomerization reaction, as suggested previously from the distributions of steroidal compounds in sedimentary basins³⁻⁵.

The relative extents to which the proposed reactions occur for steroid hydrocarbons in the sedimentary column have been suggested as being indicative of the thermal history of sediments³. These data, in conjunction with a geophysical model describing sedimentary basin formation, have been used to derive both activation energies and pre-exponential factors governing the rates of the reactions⁴⁻⁶. However, such studies have used kinetic schemes based on the following assumptions: (1) the reactions obey unimolecular first-order rate laws, and (2) the total concentration of reactant plus product remains constant throughout each reaction. In addition, rate coefficients have been derived from the relative abundances of presumed products to reactants, as measured from peak areas in mass chromatograms, rather than from absolute concentrations. The activation energy of a reaction is dependent upon its mechanism⁷; hence, if laboratory-derived values are ever to be extrapo-

lated to the sedimentary column, the same mechanism must be followed in both cases. Previous authors⁸⁻¹² have proposed the importance of free radical mechanisms in petroleum generation and associated processes. Significant concentrations of free radicals have also been measured, even at room temperature, in many kerogens¹³.

In the present study, intimate mixtures of the organic substrate, powdered sediment and elemental sulphur were heated at temperatures where high concentrations of sulphenyl and polysulphenyl radicals are observed¹⁴. Typically, the mixture in Pyrex glass tubes sealed *in vacuo* (after three N₂ purges) was heated in an oven and the temperature monitored using a chromel-alumel thermocouple. The substrate for aromatization was an isomeric mixture of ring-C monoaromatic hydrocarbons (compounds I, Fig. 1)¹⁵ and the matrix was a solvent-extracted carbonate sediment (Cretaceous, Abu Dhabi), with 0.08% w/w of elemental sulphur added. For the isomerization, one stereoisomer [(6*R*,10*S*) = *meso*-pristane] of 2,6,10,14-tetramethyl pentadecane (IIIa, Fig. 1) was used, with a solvent-extracted shale as matrix (Semécourt shale, Lower Toarcian,

Fig. 1 a, Aromatization of the 5 α (H) and 5 β (H) isomers of (20*R*)- and (20*S*)-17 β -methyl-18-norcholesta-8,11,13-triene (I) to (20*R*)- and (20*S*)-17 β -methyl-18,19-dinorcholesta-1,3,5(10), 6,8,11,13-heptaene (II) (numbering based on steroid skeleton). b, Isomerization of (6*R*,10*S*)-pristane (IIIa) to (6*R*,10*R*)- plus (6*S*,10*S*)-pristane (IIIb and IIIc respectively).

Paris Basin) plus 10% w/w of elemental sulphur. After dichloromethane extraction, quantitative product analysis was achieved by the internal standards method, using capillary gas chromatography on OV-1 (or CP-Sil 5) and DEGS/PEGs (3/1) stationary phases¹⁵.

With increasing burial depth in sediments, an increase occurs in the relative abundance of triaromatic (base peak at m/z 231 in their mass spectra; for example compounds II) to monoaromatic steroid hydrocarbons (base peak m/z 253; for example I)^{2,16}. A similar change in the aromatic steroid distribution has been observed by heating a shale in the laboratory¹⁷. Furthermore, heating experiments similar to those described here have suggested the following reaction scheme¹⁵:

where k'_A = aromatization rate constant.

If the aromatization obeys a first-order rate law, then the predicted concentration-time function $[I](t)$ for the monoaromatic steroid is:

$$[I](t) = [I](t=0) \exp(-k'_A t) \quad (2)$$

Thus, if equation (2) is correct, a plot of $\ln[I](t)$ versus time will yield a straight line with slope k'_A and intercept $\ln([I](t=0))$. In the present study, there was an exponential decrease in monoaromatic concentration with increasing time and a concomitant increase in triaromatic concentration in the early time regime. Substitution in equation (2) of experimental data from two temperatures (147.5 ± 1.5 °C and 165.0 ± 1.0 °C) are plotted in Fig. 2a. Linear regression analysis gave close to straight-line fits with calculated intercepts 5.20 (147.5 °C) and 5.13 (165.0 °C). These match satisfactorily the actual value (5.17) from the initial concentration of monoaromatic steroids. The rate constants extracted from the slopes have values of 0.0228 h^{-1} (147.5 °C) and 0.1246 h^{-1} (165.0 °C). Straight-line fits were also obtained at two other temperatures (Table 1).

The temperature dependence of a rate constant may be used to deduce the activation parameters of a reaction by use of the Arrhenius expression:

$$k = A \exp(-\Delta E_a/RT) \quad (3)$$

where R is the gas constant and T the absolute temperature.

The Arrhenius plot for k'_A , using data from Table 1, is shown in Fig. 3a. The slope yields an activation energy, ΔE_a , of 145 kJ mol^{-1} and a pre-exponential factor A , extracted from the intercept at $1/T = 0$ of $\sim 6.7 \times 10^{12} \text{ s}^{-1}$.

In immature sediments, pristane occurs predominantly as the (6R,10S)-diastereoisomer (IIIa); with increasing thermal stress, a 1:1 mixture of the (6R,10S) to the (6R,10R) plus (6S,10S) isomers is eventually formed (IIIa to IIIb plus IIIc)^{1,18}. The same effect has been observed when a shale is heated in the laboratory¹⁷. In the present work no isomerization was observed when the pure (6R,10S)-substrate was heated alone in a medium of liquid sulphur. When heated on the shale matrix with sulphur, absolute quantification reveals that, in parallel with isomeriz-

ation at C-6 and C-10, there is a degradative process depleting the total amount of pristane, as proposed previously¹⁵. These observations are consistent with the following reaction scheme:

The rate constants for the two side reactions are assumed to be equal because of the diastereomeric relationship of the product to the precursor in this acyclic alkane. Additionally, rate constants for the forward and reverse isomerization are assumed to be equal because a 1:1 equilibrium mixture of precursor and product is formed. Analysis of scheme (4), with the assumption of first-order kinetics, predicts that the concentration-time function for (6R,10S)-pristane should behave as follows:

$$[IIIa](t) = a_1 \exp(-\lambda_1 t) + a_2 \exp(-\lambda_2 t) \quad (5)$$

where

$$\lambda_{1,2} = k'_1 + k_D \pm k'_1 \quad (6)$$

The $\lambda_{1,2}$ are the roots of the auxiliary equation:

$$\lambda^2 - 2(k'_1 + k_D)\lambda + k_D(2k'_1 + k_D) = 0 \quad (7)$$

Equations (5) to (7) predict that the reactant concentration-time function should consist of two decreasing exponentials. Figure 2b shows that the experimental data fit this prediction. The solid line from linear regression analysis of points corresponding to $t > 21$ h, represents the longer-lived component ($\lambda_2 = k_D$). When this line is extrapolated to $t = 0$ and subtracted from the data points at early times ($t < 21$ h), a regression line (dashed) through the resulting residuals yields the short-lived component which has the time constant $\lambda_1 = 2k'_1 + k_D$. Thus, k'_1 at 250.2 °C is 0.1063 h^{-1} (Fig. 2b). Results for this and three other tem-

peratures are collated in Table 1. Using expression (3) and the data in Table 1, the activation parameters were extracted from the Arrhenius plot (Fig. 3b); ΔE_a has a value of 120 kJ mol^{-1} and A is $\sim 2.1 \times 10^7 \text{ s}^{-1}$.

The laboratory heating experiments show that a steroid aromatization reaction to give the m/z 231 triaromatics and a configurational isomerization reaction can be brought about in the laboratory under free radical conditions. Although first-order kinetics appear to be followed in each case, it is likely that pseudo-first-order rate constants have been measured since there is evidence that the overall rates of reaction are dependent on sulphur concentration¹⁵.

It is difficult to know at present whether these preliminary laboratory experiments, using single compound types, represent an appropriate model for the increase in extent of aromatization of aromatic steroid hydrocarbons and in the number of isomers in certain types of alkanes observed in sediments with increasing thermal stress. On the other hand, if the aromatization and isomerization reactions do indeed occur in sediments, and if free radical mechanisms operate, the laboratory ΔE_a values may be applicable to the sediment reactions. It must be recognized, however, that the apparent A factors, measured in the laboratory, are unlikely to be applicable to sediments; they are probably enhanced in the laboratory as a result of the increased concentration of radical initiator¹⁹. Despite these complexities and the fact that the laboratory ΔE_a values differ from those derived in a semi-empirical manner, using the geophysical model⁴⁻⁶, it is noteworthy that the Arrhenius plots (Fig. 3) show that the aromatization is the more temperature-dependent reaction, that is, it has larger ΔE_a (145 kJ mol^{-1}) and A ($6.7 \times 10^{12} \text{ s}^{-1}$) values than the isomerization reaction (120 kJ mol^{-1} and $2.1 \times 10^7 \text{ s}^{-1}$ respectively). Similar behaviour is implied by the relative extents of aromatization of aromatic steroid hydrocarbons and of isomerization in the side chain of steroid alkanes in that aromatization is accelerated relative to isomerization in sediments with more rapid heating rates³⁻⁵.

Palaeoclimatic and tectonic implications of Neogene microflora from the Northwestern Ethiopian highlands

Kedamawit Yemane*, Raymonde Bonnefille & Hugues Faure

Laboratoire de Géologie du Quaternaire, CNRS-Luminy, 13288 Marseille, France

Climatic changes in East Africa have been well documented although the record is far from complete. Palaeoclimatic data for both the Holocene and Pleistocene¹⁻⁷ and the Pliocene¹⁻⁸ are available through fossil pollen studies. However, these data extend in a continuous manner only as far back as 3.7 Myr BP (ref. 11) largely because of the emphasis on studies related to human origins. Fragmentary data from macrofossils also exist for older periods from Eastern¹⁴⁻²⁰, Central and Southern Africa^{21,22} although the scarcity of material and the lack of isotopic dates makes it difficult to define continuity in the patterns of climatic fluctuations in East Africa. The late Miocene pollen/spore flora described here represents the first data from East Africa for this time period and provides new information on the pre-Pliocene flora and climate of the continent. The pollen flora comes from a post-8-Myr lacustrine deposit in the heart of the Northwestern Ethiopian Plateau ($12^{\circ} 35' \text{ N}$, $37^{\circ} 06' \text{ E}$) and contains 'exotic' taxa that are now extinct. The pollen diagram is characterized by abundant wet lowland rainforest taxa and pteridophytes, a very weak representation of grasses and the total absence of conifers, indicating warm and humid climates towards the close of the Miocene. Post-depositional uplift of the Chilga area ($\sim 1,000 \text{ m}$) is also implied from the fossil pollen/spore assemblage.

The Chilga fluvio-lacustrine, lignite-bearing sedimentary sequence occurs within a graben, 60 km south-west of Gondar

* Present address: Geological Institute, Swiss Federal Institute of Technology (ETH), Zurich CH-8092, Switzerland.

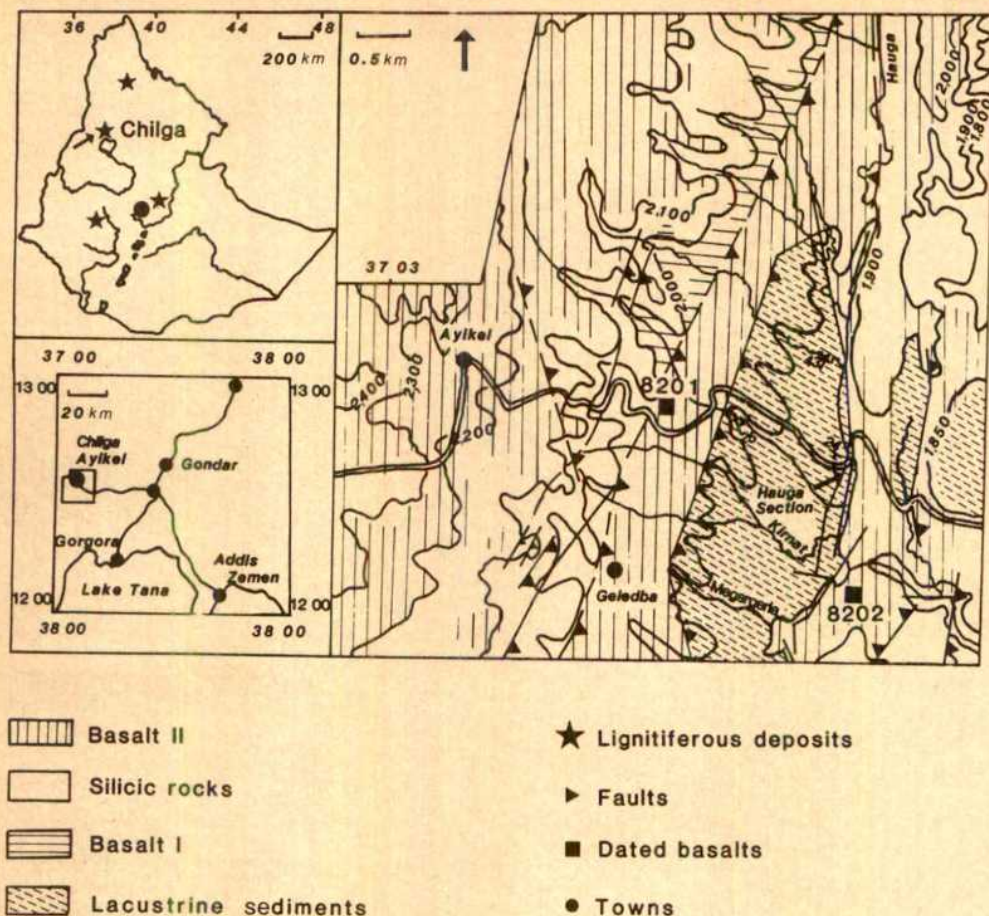

Fig. 1 Location map of Chilga and the sections studied (geological map after Tezera and Heeman²⁶).

and ~100 km north-west of Lake Tana, at altitudes between 1,900 and 2,000 m (Fig. 1). The graben is part of a large defunct Eocene rift, which ceased activity 25–20 Myr ago as the transverse-trending Afar proto-rift began to form²³. The sediments occur in one of the small north-south (NS) grabens [13 km NS by 2 km EW (east-west)] within the major Tana graben, formed by the NNE-SSW fault line running parallel to the Ethiopian Rift system. The Chilga graben is bounded on the west by highlands which rise abruptly to higher than 2,300 m. The formation of these grabens is attributed to renewed faulting activity associated with late Tertiary volcanism²⁴.

The Chilga sedimentary sequence is one of the ubiquitous continental sedimentary intercalations within the Oligo-Miocene Trap Series on the Plateau. The sequence directly overlies a basalt layer (Basalt II) which forms the graben floor. This basalt also covers the top of the westward-lying highlands and consists of numerous lava flows from separate eruptive episodes^{23,26}. It is represented by stratified, fine-grained olivine basalt (KY8201) on the highlands and is recognized along the fault line in the Chilga basin by its amygdaloidal leucite pockets and calcite veins (KY8202). Potassium-argon whole-rock analysis of two rock samples from Basalt II gave ages of 9.8 ± 0.5 and 8 ± 1.2 Myr respectively (collaboration with I. Villa, University of Pisa). The sedimentary sequence (34 m thick) commences with medium-grained basal conglomerates which fine upward to coarse-grained sandstones. It then abruptly changes to black carbonaceous mudstones which are intercalated with very fine lignite seams and thick silt layers. In the lower part, silts, clayey silts and clays dominate the section, whereas thick and consolidated lignite beds frequently occur between +15 and +30 m. A 3-m-thick water-lain volcanic ash layer crowns the sedimentary sequence.

The climate in Ethiopia is controlled by macro-scale pressure changes and monsoon flows²⁷, with elevation and topography contributing variation on the Plateau²⁸. The Northwestern Plateau is under a regime of summer rain with a mean annual rainfall of 1,000–1,400 mm distributed in one single season with

a dry period of 5–7 months²⁹. A local maximum of 1,500–1,800 mm on the mountain east of Lake Tana and 950–1,500 mm around the lake is observed¹⁸. The warmest season (25 °C) is March–May; the mean temperature on the Plateau is 5 °C cooler.

The vegetation of the Northwestern Plateau belongs to the Afromontane archipelago-like regional centre of endemism³⁰. Further south, an island of undifferentiated woodland vegetation dominated by Combretaceae associated with *Balanites aegyptica*, *Piliostigma thonningii* and *Gardenia ternifolia* form a halo around Lake Tana. Remains of evergreen montane forest with *Olea africana*, *Podocarpus gracilior*, *Juniperus procera* and *Sapotaceae* occur above 2,000 m on the well-studied east side of the Lake Tana region^{32,32}. Stands of natural vegetation have now disappeared under the pressure of human settlement³³.

Forty-six complete pollen spectra were obtained from a total of 96 studied samples collected from two outcrop exposures within the Chilga basin. Vitrinite-rich lignites and coarse detrital sediments preserved no fossils, whereas intertinite-rich lignites, carbonaceous mudstones, clays and silts yielded rich pollen and spore assemblages. Identification of fossil pollen grains was achieved with the help of a reference collection of 6,000 modern species of Ethiopian and East African flora^{34,35} and the available literature on pollen morphology^{36,37}.

We recorded 121 identified and 2 unidentified pollen taxa, with only 0.5% of unknowns on the total pollen/spore count. The Chilga fossil pollen assemblage is unique in Africa in its floral composition and diversity. This fossil flora was extensively compared with post-Eocene macrofossils from the north-west, central and south-west parts of the Ethiopian plateau^{15,18,19}, Kenya¹⁴ and Uganda²⁰; with palynoflora from central, south-east and north-east Ethiopia^{38,39}, Burundi²¹ and South Africa²²; with the modern Ethiopian flora^{35,40} and with the neighbouring East African flora⁴¹. The comparisons show three striking features in the composition of the post-8-Myr flora from Chilga, namely, the presence of 'exotic' taxa, the absence of *Podocarpus* and *Juniperus*, and the abundance of pteridophytes.

The fossil flora contains taxa that are foreign to the modern,

Fig. 2 Pollen diagram of the Chilga lacustrine deposit; relative frequencies calculated with respect to the total pollen/spore count.

Pleistocene and Pliocene pollen flora from East Africa³⁹. These include *Afrocrania volkensii*, *Brachystegia*, *Isobertlinia* type, *Iodes* type, *Holoptelea grandis* type, *Oligocodon* type and *Rauvolfia*. Although *Afrocrania* does not exist in the present Ethiopian flora⁴⁰, it is a major element of wet montane vegetations up to 3,200 m and down to lake water edges in moist montane forests in East Africa. The nearest *Brachystegia* and *Isobertlinia* vegetations are found today >1,000 km south of Chilga, in northern Tanzania, with a southward arm extending into Zimbabwe⁴¹. *Oligocodon*, a climbing shrub in tropical West Africa, has so far been recorded only from the wet rainforests of Nigeria and Cameroun³⁷. On the other hand, a taxon with pollen type indistinguishable from *Oligocodon*, *Gardenia imperialis*, grows along stream, lake and swamp margins in Uganda and Congo. *Holoptelea* is a widespread species in the Guineo-Congolian phytogeographical region as an important component of semi-evergreen lowland rainforests³⁰. The pollen of *Rauvolfia vomitoria* recorded from the rainforests of West Africa³⁷ has similar pollen types: *Rauvolfia caffra* and *Rauvolfia manni*, species which occur in montane forest vegetation in Burundi and Tanzania. The presence of these 'exotic' taxa in association with the abundant lowland taxa such as *Anthocleista*, *Mitragyna* and *Alchornea* strongly suggests a closed forest environment that is far more humid than present-day forests in the highlands of Ethiopia.

Podocarpus gracilior is a species that is a widespread component of upland forests throughout Ethiopia and East Africa. *Podocarpus* is found in East Africa in forests where the mean annual rainfall is within the range 800–1,600 mm at altitudes between 1,800 and 3,000 m. On the Western Plateau, it occurs between 1,500 and 2,200 m in nearly pure stands. *Juniperus procera*, the other associated conifer, is abundant in dry montane forests, at altitudes above 1,700 m and is also a major component

of the forest zone between 2,900 and 3,000 m altitude. The absence of a single pollen grain of either of these two conifers in a total pollen/spore count of 24,452, specially considering the excellent export ability of *Podocarpus*³, is solid evidence for the absence, on the regional scale, of present-day type upland forests on the plateau during the period of deposition. The absence of conifers is also one factor which physiognomically differentiates Guineo-Congolian rainforests from Afromontane rainforests³⁰.

More than seven different types of spores were observed in the Chilga pollen/spore flora. Except in the Upper Neogene palynoflora from Burundi²¹, which has an even more important spore flora, the Plio-Pleistocene palynoflora from East Africa does not show such diversified and abundant ferns as the Chilga pollen/spore assemblage. Elevated frequencies of pteridophytes denote an increase in rainfall and runoff⁴², thus suggesting that the Chilga fossil flora may represent the moist and shady conditions of a closed, wet forest.

Percentage frequencies of the pollen and spore assemblage are shown in Fig. 2 (detailed manuscript in preparation). This pollen diagram is condensed from the larger and more complete Hauga section (31 spectra). It comprises only taxa characterized by their high pollen concentration, consistent presence and/or generic significance. Three important features distinguish Chilga from other East African Tertiary sites.

(1) Dominance of arboreal taxa: the arboreal taxa make up >50% of most spectra (>70% if pteridophytes are excluded), a distribution pertaining to the structure of closed forests. No pollen diagram from the East African Plio-Pleistocene shows such high arboreal frequencies.

(2) Weak representation of grasses: most pollen diagrams from East Africa are characterized by high frequencies of *Gramineae* which often account for >50% of the total pollen count^{8,11,13}.

indicating widespread savanna and open woodland vegetation in the Plio-Pleistocene. In the diagram from Ghilga, the Gramineae frequencies, where present, are low, 0–27% (maximum in the moist pollen zone IIa), and the frequencies of the sedge (mostly absent) do not reach 15% (not included in this diagram). This also suggests a closed forest environment. (3) Instability of the palaeovegetation: six distinct development phases are recorded in the palaeovegetation during the depositional period. The earliest *Mitragyna* swamp forest developed extensively with *Alchornea* (Ib) at the expense of a montane-like vegetation (Ia). Through an unrecorded transition, it gave way to a deciduous *Brachystegia* forest (Ic) which further developed into a drier phase of *Combretum-Lepidagathis* woodland (Id). This vegetation was then completely replaced by an *Anthocleista-Mitragyna-Oligocodon* association of a fringing swamp and wet lowland forest (IIa). Towards the end of the period of deposition, a moist secondary forest with an *Araliaceae-Alchornea-Sapotaceae* association (IIb) became dominant, with *Sapotaceae* comprising >55% of the assemblage in the uppermost spectrum. These frequent changes from a closed swamp forest to semi-deciduous forest reflect a decrease in the humidity on the plateau.

The rate of uplift for the high plateaus of Ethiopia is thought to have increased exponentially since 100 Myr ago, from <0.05 mm yr⁻¹ to 1 mm yr⁻¹ at present⁴³, bringing the Jurassic marine limestone to its present altitude of 2,500 m (ref. 44). Epeirogenic uplift in the Cenozoic occurred at ~0.1 mm yr⁻¹ (ref. 45). If we assume a uniform uplift rate of 0.1 mm yr⁻¹, the Chilga lake beds may have risen 800 m during the past 8 Myr, which tentatively places the Chilga region at an altitude of around 1,000 m during deposition. This is also supported by the presence or absence of certain 'elevation-indicator' plant taxa in the palaeofloral assemblage. *Podocarpus* has previously been used to indicate palaeoaltitudes and to infer uplift on the Western Plateau⁴⁶. The absence of both *Podocarpus* and *Juniperus* from the Chilga palaeoflora, the modern presence of these conifers in the highlands and the location of the Chilga lacustrine deposit at an elevation of around 1,900 m suggest initial depositional altitudes of around 1,000 m for the Chilga area. Active episodes of regional tectonic and volcanic activity are also recorded from the distribution of clay minerals (<2 µm) in the sedimentary sequence which shows an abrupt increase of illite and smectite towards the top of the lake beds.

One little known but important aspect of the late Cenozoic vegetation history of Africa is the extension of tropical rainforests and the timing of the establishment of the savanna. Savanna as well as lowland rainforests and montane vegetation are thought to have occupied tropical Africa since the Miocene⁴⁶. The contraction and later disappearance of the eastern Tethys Sea during the Miocene initiated the fragmentation of the closed forest. Faunal evidence indicates a shift from lowland to woodland vegetation in tropical Africa by the mid-Miocene⁴⁷. The woodland vegetation was further fragmented by the occurrence of a widespread savanna-mosaic during the late Miocene/early Pliocene⁴⁸. Significant contraction of the tropical lowland rainforests and establishment of the savanna appears to fall within the mid-Miocene. On the Western Ethiopian Plateau, macrofossils of montane forest taxa have been recorded from several sites^{16,17}. However, no fossil record documenting lowland rainforest is available, although there exists an isolated patch of lowland rainforest³⁰ about 400 km south of Chilga. The present study, however, provides evidence for the presence of a closed forest with strong Guineo-Congolian affinities as late as 8 Myr BP as far north as 12° N on the Northwestern Ethiopian Plateau. Furthermore, the lack of datable material at the top of the sedimentary sequence allows one to speculate on a link between the late Miocene global climatic deterioration and the disappearance of the humid post-8-Myr Chilga flora. The flora may either represent the humid climate and vegetation of the Plateau before the terminal Miocene salinity crisis at 6.5–5.5 Myr BP or a relict vegetation which survived the Mediterranean aridity. Whatever the case may be, a change towards a cooler

and more arid climate in the circum-Mediterranean region that has been related to global Messinian events⁴⁹, should have noticeably affected the climate of the high plateaus of Ethiopia.

We thank G. Rioulet and G. Buchet for help in pollen identification; Drs R. Giegengack, K. Kelts and A. Shagam for helpful comments and Drs I. Friis, K. Vollesen, A. Hamilton and C. Puff for going through the pollen list. This work was supported by grants from the CNRS and CIFEG.

Archaeobacterial lipids in hot-spring microbial mats

D. M. Ward*, S. C. Brassell† & G. Eglinton†

* Department of Microbiology, Montana State University, Bozeman, Montana 59717, USA

† Organic Geochemistry Unit, University of Bristol, School of Chemistry, Cantock's Close, Bristol BS8 1TS, UK

Modern and ancient sediments contain a multiplicity of organic compounds which record a partial history of the organisms that contributed them¹. Interpretation of this record depends on the knowledge of links between the molecular markers and their biological, notably microbial, sources. This goal is made difficult

Table 1 Isoprenyl ethers (in μg per g dry weight)* of hot-spring microbial mats in Yellowstone National Park

Spring	Temperature (°C)	pH	SO ₄ ²⁻ (mM)	Archaeobacterial content† and activity	Phytanyl	Biphytanyl				Total	Average cyclization‡
						Acyclic (0)	Monocyclic (1)	Bicyclic (2)	Tricyclic (3)		
Octopus Spring (0–15 mm)	55	7.2–9.4‡	0.16	Active methogenesis/ numerous methanogens (10^7 – 10^8 cells cm^{-3})	17.2	8.5	2.3	1.5	—	12.3	0.43

—, Not detected. ND, Not determined.

* Samples of 52–8,000 mg dry weight were extracted and yielded of the order of 6 mg or less of purified alkanes derived from ethers. Peaks were identified by comparison to reference mass spectra (see ref. 17) and by spectral analysis. Peak areas were determined using a V.G. Analytical Minichrom Data System, and were corrected to concentration using response factors determined by replicate injections of standards (n -C₁₈ for phytane and n -C₂₈ for biphytanes). Coefficients of variation were 0.16–0.21.

† Methane production studied by following increases in methane during anaerobic incubation of mat samples. Estimations of methanogen population density studied by most-probable-number determination. See refs 19, 20 and 22 for details.

‡ pH determined by microelectrode (see ref. 27).

§ (% monocyclic + 2 × % bicyclic + 3 × % tricyclic) × 10⁻² after ref. 21.

|| Formulae given in Fig. 1.

by the complexity of modern sediment communities and the general lack of studies which directly tackle the relationships between the microbial inhabitants of natural systems and their associated organic compounds. We now report the first direct comparison between isoprenyl ether-linked lipids in hot-spring microbial mats and the observed populations of archaeobacteria. The particular mats examined are from Yellowstone National Park and may represent modern analogues of Precambrian communities preserved as stromatolites^{2,3}. As relatively simple microbial systems, they are suitable for validating specific molecular markers as indicators of microbial populations within a natural community. We find that the phytanyl and biphytanyl ethers reflect the measured distribution of methanogenic archaeobacteria.

An understanding of the relationships between a given biological species and its characteristic molecular markers relies on the analysis of appropriate cultures and, where possible, natural collections of that species. For many different types of land plants and algae, such procedures are relatively straightforward. For example, the link between the occurrence of 4-methylsteroids in sediments and dinoflagellates suggested by numerous sterol analyses of cultured dinoflagellates has been clearly established through direct comparison of the 4-methylsteroids of a collection taken from the water column with those of underlying sediments⁴. Similar approaches can be adopted for bacteria. For example, the occurrence of several specific acyclic isoprenoids among the free lipids of archaeobacteria⁵, a newly defined group of procaryotic microorganisms^{6–8}, grown in the laboratory was taken to suggest that they were characteristic of such organisms. Further circumstantial evidence in support of this proposition stemmed from the occurrence of these isoprenoid alkanes in sedimentary environments from which methanogenic archaeobacteria had been isolated⁹.

In addition to their free lipids, axenic cultures of representatives of the major archaeobacterial groups possess uniquely characteristic isoprenoid ethers. For example, halobacteria contain phytanyl (C₂₀)⁵ and sesterterpanyl (C₂₅)¹⁰ ethers, whereas methanogenic and other archaeobacteria (thermoacidophiles and other related organisms, such as *Thermoproteales*¹¹) produce a mixture of phytanyl and biphytanyl (C₄₀)⁵ ethers. Also, thermoacidophilic archaeobacteria can be distinguished from methanogenic archaeobacteria in that they alone are known to synthesize cyclic biphytanyl lipids⁵. All of these acyclic and cyclic isoprenoid ethers have been identified in modern and ancient sedimentary environments and fossil fuels¹² through chemical analysis. Such investigations have led to the suggestion that cyclic biphytanyl ethers are not restricted to thermoacidophiles, but may occur in methanogens¹³. An alternate interpretation is that other nonmethanogenic archaeobac-

teria are (or were) unknown inhabitants of sediments in which these cyclic biphytanyl ethers are found.

Clearly, a better understanding of the link between molecular markers and their microbial sources is desirable. For microorganisms, the traditional approach to the enrichment and isolation of axenic cultures does not ensure recovery of all the members of natural communities. Thus, the extent to which existing collections of axenic cultures (and their molecular markers) are representative of the total variety of organisms (and organic chemicals) in a given environment is not known. Lipids have been used as biochemical markers to assess directly the microbial community structure of sediments^{14,15}, but the complexity of sediment communities can seriously limit attempts to establish firm and direct relationships between organisms and their marker lipids. We have, therefore, begun investigations of such relationships in relatively simple systems, that is, hot-spring microbial mats, where high temperatures and/or acidity limit the diversity of their wholly microbial communities. However, microbial processes that control elemental cycles in these mats are similar, in principle, to those found in other aquatic systems¹⁶. These mats are also modern analogues² of the abundant Precambrian microbial communities recorded as stromatolites in the sedimentary record³. The significance of stromatolites stems from their status as a primary manifestation of life on Earth and, thus, they have a key role in the understanding of early evolution. The simplicity of the hot spring community reduces the problems of defining the relationships between organisms and molecular marker compounds. Yet, these mats are relevant analogues to the interpretation of microbial community structure in modern and ancient sediments and mats.

Samples were collected from microbial mats in three springs of Yellowstone National Park, Wyoming, USA (Table 1), using solvent-rinsed materials, immediately frozen, and lyophilized. They were treated directly with BBr₃ to release ether linked lipids as bromides, which were reduced to alkanes or D-labelled alkanes using LiAlH₄ or LiAlD₄, respectively¹⁷. Alkanes were analysed quantitatively by glass capillary gas chromatography and identified by computerized gas chromatography-mass spectrometry (C-GC-MS)¹⁸ by comparison with reference mass spectra for biphytane and its monocyclic analogue¹⁷, or by spectral interpretation. The degradative procedures released isoprenoid hydrocarbons in all samples (Table 1). The D-labelling suggested that these hydrocarbons originated from phytanyl monoethers and biphytanyl diethers.

Octopus Spring is an alkaline spring low in sulphate in which methanogenesis is active^{19,20}. Here, the highest concentrations of archaeobacterial lipids were observed in the 55 °C mat (Table 1) with phytanyl and biphytanyl ethers in approximately equal

Table 2 Depth distribution of isoprenyl ethers (in μg per g dry weight)* in Octopus Spring mat

Depth interval (mm)	Phytanyl	Biphytanyl			Total	Average Cyclization*
		Acyclic† (0)	Monocyclic (1)	Bicyclic (2)

† Formulae given in Fig. 1.

abundance. This lipid distribution resembles that of *Methanobacterium thermoautotrophicum*⁵, the only methanogenic bacterium as yet isolated from this mat²⁰. The concentrations of these compounds within the mat were similar to the distribution of methanogenic bacteria and methanogenesis in the mat. They were higher at 55 °C than at 70 °C (Table 1), where methanogenesis is slight and methanogens are orders of magnitude less numerous^{19,20}.

The vertical distribution of isoprenyl ethers in the 55 °C Octopus Spring mat reveals that the highest concentrations occur in the 3-6 and 6-9 mm depth intervals (Table 2). This profile is consistent with that of methanogenesis which is most active in the 1-5 mm depth interval¹⁹. Our current method of analysis cannot, however, distinguish the complex polar lipids of living methanogenic bacteria from their degradation products retaining the isoprenyl cores. Hence, the ether cleavage products at depth in the mat may derive, in part, from the relict lipids of inactive methanogens, since methanogenesis does not occur below about 5 mm in the mat. Certainly, the isoprenoid glyceryl ethers survive in ancient sediments and even in pre-troleum¹².

Cyclic biphytanyl ethers were detected in the Octopus Spring mat (Fig. 1a), although they have not been reported in *M. thermoautotrophicum* or other methanogenic bacteria. Rather, they are representative of thermoacidophilic and related archaeobacteria, but such organisms have not been isolated from mats of alkaline springs. The unexpected presence of cyclic biphytanyl ethers in this mat parallels that of the discovery of cyclic biphytanyl ethers in marine sediments and fossil fuels^{12,17}. It may be due to either lipid inputs from other archaeobacteria, or a lack of complete understanding about methanogen lipids. The simplicity of the hot-spring mat community should permit a test of the first hypothesis, and we are now developing methods to do so. The higher degree of cyclization in biphytanyl ethers observed at 70 °C than at 55 °C (Table 1) may be due either to different archaeobacterial populations, or to the influence of temperature on the lipids of a single organism. For example, *Calderiella acidophila*, a thermoacidophilic archaeobacterium, shows greater cyclization of biphytanyl ethers with increasing growth temperature²¹. Cyclization also varied with depth, but no specific trend with depth was noted.

Painted Pool is a neutral spring high in sulphate. Although methanogenic bacteria may be enriched from such high sulphate environments^{22,23}, they exist at low population density and their activity is suppressed by sulphate reduction²². These environmental features are mirrored in the low concentration of phytanyl ethers and absence of biphytanyl ethers (Table 1). Similar results have been reported for methanogen lipids in lacustrine compared to marine sediments¹⁵, where methanogenesis is limited by the level of sulphate available in the sediment²⁴.

Nymph Creek is an acid spring of 47 °C which might harbour thermoacidophilic archaeobacteria²⁵. Here, cyclic biphytanyl ethers dominated over their acyclic counterpart (Table 1; Fig. 1b), with bicyclic components the most abundant. Tricyclic biphytanyl ethers were only detected in low concentration (Table 1). Similar features have been reported for thermoacidophilic

Fig. 1 Glass capillary gas chromatograms of alkanes derived from the ether cleavage procedure from: *a*, Octopus Spring 55 °C mat, 12-15 mm depth; and *b*, Nymph Creek 47 °C mat, ~0-1 cm depth. Samples were analysed on a Carlo Erba model 4160 gas chromatograph with a 50 m CPSil5CB WCOT column with H_2 carrier gas. Samples were injected on column at ~35 °C, and temperature was rapidly increased to 80 °C, then programmed to increase at 4 °C min^{-1} to 300 °C. Oven temperature was then kept isothermal at 300 °C (beginning at a run time of 55 min). Output from the flame ionization detector was processed on a V.G. Analytical Minichrom data system. Individual peaks were quantified by reference to the peak area responses of standard *n*-alkanes. *n*-alkanes were removed by urea adduction²⁶ before analysis of the sample shown in *a*. 2', 2'' = isomers of bicyclic biphytane¹².

archaeobacteria³, but despite numerous attempts, such organisms, especially *Thermoplasma*, have not been isolated from this mat²⁵. The only other known thermoacidophilic archaeobacterium which might inhabit this mat is *Sulfolobus*, but apparently it cannot be enriched from acid environments at temperatures as low as that of this mat²⁵. Other related archaeobacteria (*Thermoproteales*) would not be expected¹¹ to grow at this temperature and pH. Thus, the observation of archaeobacterial lipids in this hot acid mat illustrates our incomplete understanding of the microbial inhabitants of this system and suggests the presence of archaeobacteria which have thus far eluded enrichment and isolation.

This geochemical study of a well characterized environment provides evidence for the correspondence between the distributions of specific molecular markers for methanogens and the organisms themselves. Such assessments of the organisms contributing to a given environment using molecular markers are inevitably limited by the available information on the biological occurrences of the compounds. However, where diagnostic markers are found they can provide direct evidence of the activity of specific microorganisms. In modern environments, diagnostic molecular markers may reveal the presence of otherwise unknown community members. By contrast, the absence of such molecular markers cannot always be taken as indicative of a lack of contributions from the relevant organism, since biological and chemical alterations of organic compounds may occur

after biosynthesis, but before analysis. In addition, it is inappropriate to argue that molecular markers provide a quantitative assessment of the importance of individual organisms as sources of organic matter in general, especially when the compounds are present at levels <100 p.p.m. (parts per 10⁶).

We thank Sr F. Cassani for helpful advice and assistance. This work was supported by a guest research fellowship from The Royal Society. The C-GC-MS facilities were provided by the Natural Environment Research Council (GR3/2951 and GR3/3758) and the GC data system was funded by The Royal Society. Field work was supported by the NSF under grant no. BSR-8315279. We thank the United States National Park Service for permission to collect samples in Yellowstone National Park.

Complementary DNA sequences of ovarian follicular fluid inhibin show precursor structure and homology with transforming growth factor- β

Anthony J. Mason, Joel S. Hayflick, Nicholas Ling*, Frederick Esch*, Naoto Ueno*, Shao-Yao Ying*, Roger Guillemin*, Hugh Niall† & Peter H. Seeburg

Departments of Molecular Biology and † Protein Biochemistry, Genentech, Inc., 460 Point San Bruno Boulevard, South San Francisco, California 94080, USA

* Laboratories for Neuroendocrinology, Salk Institute for Biological Studies, 10010 North Torrey Pines Road, La Jolla, California 92037, USA

Inhibin, a specific and potent polypeptide inhibitor of the secretion of follicle-stimulating hormone (FSH)¹, of gonadal origin and thus a potential contraceptive, may constitute a missing link in the mechanism controlling the differential secretion of the pituitary gonadotropins. Inhibin-like bioactivity has been reported in various fluids and extracts of testis²⁻⁵ and in ovarian follicular fluid⁶⁻¹⁰. Although there have been several attempts to purify inhibin from

seminal plasma¹¹⁻¹³, purification from follicular fluid has been more successful (refs 14-16; for review see ref. 17). We have previously isolated two forms (A and B) of inhibin from porcine follicular fluid¹⁴. Each form comprised two dissimilar subunits of relative molecular mass (M_r) 18,000 (18K, referred to here as the α -subunit) and 14K (the β -subunit), crosslinked by one or more disulphide bridge(s). Forms A and B differ in the N-terminal sequence of their 14K subunit. Preliminary structural characterization of porcine¹⁵ and bovine¹⁶ ovarian inhibins shows that they have similar properties. Here, we have used the N-terminal amino-acid sequence data on the subunits of each inhibin to identify cloned complementary DNAs encoding the biosynthetic precursors and report that inhibins are the product of a gene family that also includes transforming growth factor- β (TGF- β) and whose structural organization is similar to that of pituitary and placental glycoprotein hormones.

The strategy for identifying clones containing coding sequences for the inhibin subunits was based on the 'long-probe' approach^{18,19}. A high-complexity cDNA library constructed in the vector λ gt10 and derived from porcine ovarian messenger RNA by oligo(dT)-primed cDNA synthesis was screened with a single 64-base synthetic oligodeoxynucleotide directed against the N-terminal amino-acid sequence of the porcine inhibin α -chain. Sequence analysis of several hybridizing cloned cDNAs confirmed correct probe identification and revealed that none of the cDNAs characterized encoded the complete structure of the α -chain precursor protein.

A second library was constructed by 3' extension on ovarian mRNA of a synthetic oligodeoxynucleotide complementary to a sequenced region encoding α precursor residues 60-64 (Fig. 1a). This library was screened with a suitable restriction fragment from a previously analysed cDNA and yielded several isolates which specified the remainder of the DNA sequences encoding the N-terminal region of the α precursor. The full sequences for the precursor protein and its cDNA are shown in Fig. 1b. The complete protein consists of 364 amino acids ($M_r \sim 39K$), of which the C-terminal 134 constitute the α -subunit. The pair of arginines preceding these 134 residues probably constitutes the site for proteolytic release of the α -subunit from its precursor. The pro-region of this precursor contains additional arginine pairs, suggesting the possible existence of other bioactive peptides within this precursor. The precursor protein sequence predicts two N-linked glycosylation sites, one within the α -chain proper. Glycosylation could account for the difference in size between that deduced from the amino-acid sequence ($M_r \sim 14.5K$) and the M_r of 18K obtained by gel electrophoresis¹⁴.

The cDNA sequences encoding the precursors of the inhibin β -subunits were obtained from the same cDNA libraries as used for the α -subunit. Overlapping cDNA clones were isolated by screening first with single long synthetic oligodeoxynucleotide probes based on the two N-terminal β -subunit sequences and subsequently with suitable restriction fragments derived from characterized cDNA clones which served as probes for 'walking' in both 5' and 3' directions (Fig. 2a).

Only four out of 2×10^5 clones from the oligo(dT)-primed library hybridized with the synthetic probe for the β -subunit of inhibin A. Three of these clones proved correct by DNA sequence analysis, but none contained a full 3'-untranslated region, as judged by the absence of a poly(A) homopolymer at their 3' ends. Unexpectedly, a higher abundance (~ 10 -fold) of inhibin β_A -subunit coding sequences was found in the cDNA library made by specific priming on α -subunit mRNA. This library was screened with the synthetic probe for the β -chain of inhibin A on our subsequently refuted working hypothesis that the α precursor mRNA might also encode the β -subunit. The high abundance of inhibin β_A cDNA in this library was later traced to a fortuitous complementarity of the specific α -chain primer to a region in the 3'-untranslated part of the β_A mRNA.

Only four cloned cDNAs encoding the β -subunit of inhibin B were found in our libraries. The sequence information

Ovarian total and polyadenylated RNAs were analysed by the Northern procedure to assess size and relative abundance of the mRNAs encoding the peptide subunits of both forms of inhibin. DNA sequences encoding the divergent pro-regions of β_A and β_B were used as hybridization probes in stringent conditions. Analysis showed (Fig. 3) that α and β mRNAs are of different size and abundance, confirming results obtained from

Fig. 2 Inhibin β -subunits; nucleotide sequence of cDNAs and predicted primary structure of precursors. **a**, Schematic representation of the porcine β_A and β_B -subunit mRNAs with coding sequences boxed. The β_A and β_B -subunits (cross-hatched boxes) are encoded towards the 3' end of the coding sequences. The 3'- and 5'-untranslated regions are shown as a line. The length of the 5' end of β_A mRNA and the 5'- and 3'-untranslated regions of the β_B -subunit mRNA are inferred from the size of the mRNAs (Fig. 3) and the obvious similarity of β_B to β_A mRNA. Regions of the cDNAs not obtained by cloning are shown as dashes in the diagram. The relative positions of the overlapping oligo(dT)-primed cDNA clones and the randomly primed clones (λ PIN- β_A 5s, λ PIN- β_B 1s and λ PIN- β_B 2s) are indicated. The scale is in nucleotides from the 5' end of the 4.5-kb mRNA. **b**, Sequence comparisons. Nucleotide numbers on the left refer to those of cloned β_A cDNA sequences. Amino-acid numbers are for β_A precursor residues. The N-termini of the β -subunits, which are preceded by basic processing sites (black bars), are indicated by arrows. The β_B sequence is shown underneath the β_A sequence and aligned with it for maximum homology. Regions containing identical amino-acid sequences are boxed. Cysteine residues are shaded, possible processing sites are indicated by open bars, and potential glycosylation sites are shown by cross-hatched bars. A highly G+C-rich region 3' to the termination codon is underlined in one and overlined in the other sequence, and the AATAAA polyadenylation signal is underlined in the β_A -subunit sequence. There was one nucleotide difference between λ PIN- β_A 8 and the other clones covering this area: a G \rightarrow A change at nucleotide 868 results in a change of amino-acid 278 from a glycine to a serine. Another polymorphism was observed at amino-acid 206 in the β_B -subunit sequence shown, where the T \rightarrow C change found only in λ PIN- β_B 1 would result in a Phe \rightarrow Leu change.

Methods. Approximately 2×10^5 oligo(dT)-primed ovarian cDNA clones were screened with the 5'-³²P-labelled β_A oligonucleotide, 5'-AAGAAGCAGTTC-TTTGTGTCCTCAAGGACATTGGCTGGA-ATGACTGATCATTCG-3', based on the amino-acid sequence (residues 321-339). Four hybridization positives were obtained, of which three proved to contain β_A coding sequences (λ PIN- β_A 2, β_A 4, β_A 8). A 5'-end 157-bp *Eco*RI/*Hind*III (nucleotides 158-298) fragment and a 3'-end 221-bp *Eco*RI/*Pst* fragment (nucleotides 1,681-1,885) derived from λ PIN β_A 2 were used to screen 2×10^6 oligo(dT)-primed cDNA clones and 2×10^5 clones from the specifically α -chain primed library. Of the 16 clones analysed in detail, 2 were found to have longer 5' ends (λ PIN- β_A 5s, β_A 22) and 1 (λ PIN- β_A 21) contained the entire 3'-untranslated region. The *Eco*RI restriction sites do not refer to sequences present in the cDNA but are all contained within the cDNA adaptor fragment and thus add an extra 16 nucleotides to the above fragment sizes. Porcine inhibin β_B -subunit cDNA clones were isolated by screening 2×10^5 clones from the specifically primed library with the β_B oligonucleotide, 5'-GGCTGGAGTGTGATGGGAGACCAACCTGTCTCCGCCAGCAGTTC-TTCATCGATTTCAGGCT-3', which was based on the NH₂-terminal sequence described in Fig. 1a legend. Positive clones were further screened with the oligonucleotide inosine probe 5'-AAITCTAIAIA-ACTG¹TG-3' containing deoxyinosine³⁵, which covers all the possibilities in the noncoding strand for the amino-acid sequence QOFFIDE. Two clones (λ PIN- β_B 1s, β_B 2s) were sequenced and found to code for the β_B -subunit. A 231-bp *Eco*RI/*Sma* (nucleotides 406-630) fragment was isolated from λ PIN β_B -1 and used as a hybridization probe to screen 2×10^6 oligo(dT)-primed cDNA clones. Two positives were obtained (λ PIN- β_B 3, β_B 4). The nucleotide sequence of these overlapping clones was used to construct the sequence shown. All sequences were obtained by subcloning specific fragments into M13 phage vectors^{33,34}.

Fig. 3 Northern analysis of mRNA for inhibin subunits α , β_A and β_B . Lanes *a*, *b*, *c*, *d* and *f* contain poly(A)⁺ RNA and lanes *e* and *g* contain total RNA. The positions of the 28S and 18S ribosomal RNAs are indicated by arrows. Lanes *a*, *d* and *e* were hybridized with an α -subunit cDNA probe, lanes *b*, *f* and *g* with a β_A -subunit-specific probe, lane *c* with a β_B -subunit-specific probe. The α -subunit mRNA is ~1.5 kb long, the β_A -subunit mRNAs are ~4.5 and 7.2 kb, and the β_B -subunit mRNA is ~4.5 kb long. The hybridizations shown in lanes *a*, *b* and *c* were performed with probes of approximately equal length and specific activity in order to judge relative mRNA levels.

Methods. Polyadenylated RNA (2 μ g, lanes *a*, *b*, *c*, *f*; 8 μ g, lane *d*) and total RNA (10 μ g, lanes *e*, *g*) were electrophoresed into a formaldehyde-1.2% agarose gel containing formaldehyde as a denaturant³⁶ and blotted onto a nitrocellulose filter³⁷. The following ³²P-labelled cDNA fragments were used as hybridization probes. Lane *a*, 258-bp *EcoRI/SmaI* (nucleotides 131-371) from α -subunit cDNA λ PIN- α 2; *b*, 157-bp *EcoRI/HindIII* (nucleotides 158-298) from β_A -subunit cDNA λ PIN- β_A 2; *c*, 231-bp *EcoRI/SmaI* (nucleotides 406-630) from β_B -subunit cDNA λ PIN- β_B 1; *d*, *e*, *EcoRI* insert of λ PIN- α 2; *f*, *g*, *EcoRI* insert of λ PIN- β_A 4. Filters were washed for 2 h with three changes of 0.1 \times SSC, 0.1% SDS at 60 °C.

cDNA cloning. From their respective band intensities, the α precursor mRNA is estimated to be in at least 10-fold higher abundance than the mRNA for the β_A precursor, and ~20-fold higher than the β_B precursor mRNA.

Using ribosomal RNAs as size standards, the α precursor mRNA, a single species, is found to be ~1,500 nucleotides long, in good agreement with the cloned cDNA sequence (Fig. 1*b*). β_A Precursor mRNA sequences are represented by two main species of ~4.5 and ~7.2 kb. The uniformly higher intensities of α and β_A species in polyadenylated than in total RNA (Fig. 3, lanes *d*-*g*) suggest that the β_A 4.5-kb species does not represent an artefact created by 28S RNA hybridizing to the cDNA probe. The β_A precursor cDNA sequences shown in Fig. 2*b* are therefore thought to be complementary to this 4.5-kb mRNA. The difference in size from the 3.6-kb-long cloned cDNA is attributed to missing 5' sequences. Unusually long 5'-untranslated regions are not without precedent²⁰⁻²². A differential splicing event or choice of a different polyadenylation signal might explain the existence of the 7.2-kb mRNA^{23,24}. The β_B precursor is encoded by a single mRNA of ~4.5 kb and is present at approximately half the level of the two β_A mRNAs.

The mature inhibin α - and β -subunits contain seven and nine cysteine residues respectively. Alignment of these residues shows that both types of subunits share a similar cysteine distribution and that some sequence homology exists around these residues (Fig. 4*a*), suggesting that α - and β -subunits are derived from one ancestral gene. Surprisingly, significant homology was found between the β -type sequence and the recently determined primary structure of human TGF- β ²⁰. As outlined in Fig. 4*b*, these peptides are of nearly equal length (inhibin β_A subunit, 116 residues; β_B subunit, 115; TGF- β , 112) and show a strikingly similar distribution of their nine cysteine residues. Using this cysteine 'pattern' for alignment, the β_A and TGF- β sequences

Fig. 4 Sequence homologies of inhibin subunits and TGF- β . *a*, Comparison of porcine inhibin β_A and α -subunit sequences. Numbers refer to the mature subunit sequences. *b*, Comparison of human TGF- β ²⁰ and porcine inhibin β -subunit sequences. Amino acids are shown in the one-letter code. Identical residues are boxed with cysteine residues shaded. Asterisks denote conservative changes.

have an additional 33 residues in identical positions and show conservative changes in more than 10 places. Similar homologies are seen on comparison of the β_B and TGF- β sequences. The β -subunit of inhibin is unlikely to be the porcine equivalent of human TGF- β , as there is almost absolute homology between human and murine TGF- β (R. Derynck, personal communication). Sequence homology extends into the pro-region where the inhibin β and TGF- β precursors²⁰ show similar hydrophobicity profiles (data not shown). Certain features of their cDNAs, in particular the highly G + C-rich sequence following the termination codons, may further attest to a common origin. Our findings strongly indicate that both inhibin subunits and TGF- β belong to one gene family and are biologically active as dimeric structures in which the subunits are linked by disulphide bridges^{14,25}.

The structural organization of porcine ovarian follicular fluid shares some intriguing features with the pituitary and placental glycoprotein hormones, FSH, luteinizing hormone (LH), thyroid stimulating hormone and chorionic gonadotropin²⁶. Like these molecules, inhibins A and B are high-*M_r* glycoproteins and have two subunits, one of which is common to both forms, the other variable, all encoded by different mRNA species. The mRNA encoding the common (α) subunit in both structures is in substantially higher abundance than the corresponding β -subunit mRNA, suggesting a similarity in the regulation of biosynthesis of each group of hormones²⁷. In the abovementioned hormones, the 'variable' (β) subunit confers the different biological specificities of each molecule, while the 'constant' (α) subunit presumably has a crucial role in folding and overall conformation of the complex²⁶. We have no evidence for differences in the biological properties of inhibins A and B. Unlike the known glycoprotein hormones, the two chains of both inhibins A and B are linked by disulphide bridges, a situation more closely resembling the immunoglobulins²⁸.

Regarding biosynthesis, each inhibin chain is released through proteolytic processing of a larger precursor, the α - and β -subunits representing the C-terminal region of each polypeptide. The discrepancy in size between the larger subunits of bovine¹⁶ and porcine inhibins can be readily explained by a different processing of their precursors.

The precursors for the porcine inhibin subunits have several common structural features: they carry the subunits at their C-termini, are similar in total size, have typical signal sequences at their N-termini and show a remarkably similar distribution of cysteine residues. In fact, closer analysis reveals significant sequence homology between the α - and β -subunits suggestive of an origin from distantly related genes. This, too, is a feature of the subunits constituting the pituitary and placental glycoprotein hormones²⁶.

Of considerable interest is the high homology of inhibin β -subunits with TGF- β , which points to an evolutionary link between the corresponding genes. It is intriguing that members of this distinctive gene family should be involved in such seemingly unrelated activities as the control of reproduction and cellular growth. What determines the activities of their respective protein products?

A clue may be found in the fact that TGF- β is active in a homodimeric form more homologous in amino-acid sequence to the β -subunits than to the α -subunit of inhibin. This fact and the analogy with the glycoprotein hormones noted above, direct attention to the β -subunits as the possible source of biological specificity of inhibin. Chain recombination experiments to generate novel heterodimers between inhibin and TGF- β subunits could test this hypothesis. Moreover, it is tempting to speculate that inhibin could function as a paracrine or autocrine growth regulator within gonadal tissue.

The prediction of the full inhibin structures from cloned cDNA sequences has allowed us to obtain specific antibodies against synthetic peptides based on these sequences, which are currently used to study inhibin regulation. The availability of cloned DNA sequences for inhibins will help to characterize the expression of these genes in gonads and possibly other tissues. More importantly, the recombinant expression of these sequences will allow the elucidation of their physiological role at the gonadal, pituitary and hypothalamic level.

We thank the Genentech Organic Chemistry group for synthesis of oligodeoxynucleotides, Drs Rik Derynck and Karoly Nikolics for critical reading of the manuscript, and Jeanne Arch for its preparation. This research was supported by Genentech, Inc. and by Program Project grants HD09690 and AM18811 awarded to the Laboratories for Neuroendocrinology at the Salk Institute.

Epidermal growth factor receptor occupancy inhibits vaccinia virus infection

Vaccinia virus encodes VGF, an early protein of relative molecular mass 19,000 (19K) which, from amino-acid residues 45 to 85, is homologous in 19 residues to epidermal growth factor (EGF), and transforming growth factor- α (TGF- α)^{1–3}. The conserved sequence includes a region of high homology (6 out of 10 amino acids) from residues 71 to 80, corresponding to the third disulphide loop of both EGF and TGF- α . This region has recently been shown to contain a binding region of TGF- α for the EGF receptor⁴, and this raises the question of whether vaccinia virus utilizes the EGF receptor in order to bind to and infect cells. We now show that occupancy of the EGF receptor inhibits vaccinia virus infection. Inhibition is observed in a dose-dependent fashion by pre-treatment with either EGF or synthetic decapeptide antagonists of EGF's mitogenic activity which correspond to the sequence of the third disulphide loop of VGF or TGF- α . The relative ability of the peptides to inhibit vaccinia virus infection parallels their binding affinity to the EGF receptor.

In order to test the concept that vaccinia virus makes use of the EGF receptor to infect cells, the effects of EGF and peptide antagonists of EGF were studied in a viral replication assay. Treatment of murine L-cells with EGF prior to the addition of vaccinia virus (strain WR; American Type Culture Collection) for a 1-h adsorption period inhibited viral infection in a dose-dependent manner, as monitored by a plaque reduction assay (Fig. 1). Further addition of EGF after the initial 1-h adsorption period and for the 4-day duration of the plaque assay resulted in a slight additional decrease in viral plaque number. Similarly, addition of synthetic decapeptide antagonists^{4,5} corresponding to the third disulphide loop of VGF or TGF- α (Fig. 2) resulted in a dose-related reduction in the number of viral plaques (Fig. 1). Further analysis of inhibition of single-cycle vaccinia virus replication by EGF of the synthetic decapeptides showed that whereas inhibition was achieved by EGF or decapeptides when the peptides were present before and during viral adsorption, no inhibition was observed when the peptides were added 2 h after viral adsorption. The additional decrease in viral plaque formation in the multi-cycle plaque assay when the peptides were also added 1 h after initial viral adsorption (Fig. 1) can be attributed both to inhibition of adsorption which was not complete in 1 h (which was confirmed in single-cycle virus yield experiments) and inhibition of viral adsorption in subsequent replication cycles.

The ability of EGF and the synthetic peptides to inhibit vaccinia virus replication correlated with their affinity for the EGF receptor on the L-cells (Fig. 3). EGF inhibited vaccinia virus plaque formation by approximately 50% at a concentration of 10^{-8} M (compared with 10^{-9} M for 50% maximal binding). The synthetic decapeptide antagonists (N and C terminal capped) which were approximately 10^3 times lower in EGF receptor

Fig. 1 Inhibition of vaccinia virus plaque formation by EGF and related synthetic decapeptides. Plaque reduction of vaccinia virus in L fibroblasts was performed as described elsewhere¹². EGF was purified from mouse submaxillary glands⁴. Peptide compounds were added to cells 3 h before viral adsorption as well as being left in the presence of cells during a 1-h viral adsorption period (open symbols); or were added both before and during viral adsorption as well as in the agar overlay after aspiration of the inoculum virus (solid symbols). Values plotted are the mean of three replicates \pm s.d. *a* = \circ , \bullet , EGF; \square , \blacksquare , acetyl TGF- α (34-43)-NH₂; \triangle , \blacktriangle , H-TGF- α (34-43)-OH (virus control was 38.8 ± 4.1 plaques, average of 6 replicates). *b* = \circ , \bullet , EGF; \square , \blacksquare , acetyl VGF(71-80)-OMe; \triangle , \blacktriangle , acetyl VGF(71-80)-NH₂ (virus control was 33.7 ± 1.0 plaques, average of 6 replicates).

affinity, showed a similar decreased potency relative to EGF for the inhibition of vaccinia virus replication. The corresponding 'free acid' decapeptide, which was less effective in binding to the EGF receptor, was similarly less effective in preventing vaccinia virus plaque formation. The fact that complete inhibition of vaccinia virus infections was not obtained at concentrations of EGF or peptides that were saturating in terms of binding to the EGF receptor suggests that, although initial interaction of VV with the EGF receptor may lead to productive infection, it is not the only pathway by which VV can infect L cells. Recently Stroobant *et al.*¹³ reported that VV was able to infect NR-G cells which lack detectable EGF receptors.

Specificity of the inhibition of vaccinia virus replication by EGF and the homologous synthetic peptides was confirmed by (1) lack of inhibition of vaccinia viral plaque formation or

Fig. 2 Peptide sequence of EGF, VGF and the TGF- α third disulphide loop, and sequences of the synthetic decapeptides. Sequence homologies between all peptides are boxed. TGF- α peptides and VGF peptides were synthesized using solid-phase techniques as described for the TGF- α peptides^{4,5}.

Fig. 3 Inhibition of binding of ¹²⁵I-EGF to L-cells. EGF was radioiodinated with Enzymobeads (Bio-Rad) to 120,000 c.p.m. per ng protein⁴. Receptor binding on L-cells was performed as previously described for A431 cells⁴. Nonspecific binding (determined in the presence of 100 times excess cold EGF) was $\leq 15\%$ of the specific binding; approximately 40,000-50,000 specific high-affinity binding sites were found per cell. L-cells were incubated at 4°C with 1 nM ¹²⁵I-EGF in the presence of EGF(\bullet), acetyl TGF- α (34-43)-NH₂(\square), H-TGF- α (34-43)-OH(\triangle), acetyl VGF(71-80)-OMe(\blacksquare), acetyl VGF(71-80)-NH₂(\blacktriangle) or H-VGF(71-80)-OH(\blacktriangledown). Average of 3 replicates plotted; s.d. $\leq 5\%$.

single-cycle virus yield by two unrelated polypeptides which bind to their respective receptors on L-cells, that is, insulin ($1 \mu\text{g ml}^{-1}$) or bovine growth hormone ($1 \mu\text{g ml}^{-1}$); and (2) no inhibition of two unrelated viruses by EGF or synthetic peptide (an RNA virus, vesicular stomatitis virus, Indiana strain, on L-cells; or a DNA virus, herpes simplex virus type II, strain G, on Vero cells).

It is noteworthy that EGF, which is an agonist in stimulating cellular DNA synthesis, and the synthetic decapeptides, which are antagonists of the mitogenic effect of EGF^{4,5}, both appear to inhibit vaccinia virus receptor interaction, with subsequent inhibition of viral replication. These results suggest that (1) it is likely that the inhibition occurs through blocking of the receptor site utilized by the virus and not by an indirect phenomenon after activation of the EGF-receptor system, and (2) a mitogenic effect of the native vaccinia virus 19K protein is not an obligatory requirement for viral replication. Recently, a vaccinia virus 25K protein (isolated from supernatants of

vaccinia virus-infected cells) was shown to bind to the EGF receptor and to have cellular mitogenic activity⁶. It remains to be demonstrated whether this protein corresponds to the 19K protein¹⁻³ bearing homology to TGF- α and EGF. It is possible that the growth factor secreted by vaccinia virus-infected cells may account for cellular hyperproliferation as previously suggested^{1,6}, as well as contribute to the self-limiting nature of vaccinia virus lesions.

The cellular receptors for certain viruses have been identified as being receptors for various other specific ligands. For example, Epstein-Barr virus infects B lymphocytes via the complement receptor CR2 (ref. 7); rabies virus may utilize the acetylcholine receptor⁸; the human T-cell lymphotropic virus type III (HTLV-III) receptor on T lymphocytes contains the CD4 (or T4) antigen^{9,10}; and the reovirus receptor has recently been identified as the cellular β -adrenergic receptor¹¹ (G. Gaulton, personal communication). Our results now provide another example of a virus that appears to utilize a cellular receptor specific for a physiological ligand.

We thank Dr A. C. Allison for helpful suggestions and comments. This is contribution no. 226 from the Syntex Institute of Bio-Organic Chemistry.

Characterization of receptors for human tumour necrosis factor and their regulation by γ -interferon

Bharat B. Aggarwal, Thomas E. Eessalu & Philip E. Hass

Department of Protein Biochemistry, Genentech, Inc., 460 Point San Bruno Boulevard, South San Francisco, California 94080, USA

Tumour necrosis factors, TNF- α and TNF- β (previously called lymphotoxin), are the products of activated monocytes and lymphocytes, respectively, and both have recently been purified, sequenced and cloned by recombinant DNA methods¹⁻⁵, revealing 35% identity and 50% homology in the amino-acid sequence. Both proteins have been found to be specifically toxic to many tumour cells. Furthermore, it has been reported that various interferons are synergistic with TNF for anti-tumour effects *in vitro*⁶⁻⁸, while activities attributed to the two proteins have also been shown to necrotize various tumours *in vivo*^{2,3,9}. We have now prepared ¹²⁵I-labelled highly purified recombinant human TNF- α to study in detail its binding to the human cervical carcinoma cell line ME-180. Our results indicate that there is a single class of specific high-affinity receptors for TNF on this cell line which has a K_d of about 0.2 nM and an average of 2,000 receptor sites per cell. The binding of labelled TNF- α to these cells can be inhibited by both TNF- α and TNF- β but not by γ -interferon (IFN- γ). However, preincubation of cells with IFN- γ increases the total number of TNF receptors two to threefold without any significant change in the affinity constant. This is the first report that TNF- α

Fig. 1 SDS-polyacrylamide gel electrophoresis (a) and Mono Q-fast protein liquid chromatography of iodinated TNF- α (b). The autoradiographs shown in a represent samples from three different iodinations (lanes 1-3). About 10,000 c.p.m. of ¹²⁵I-TNF were analysed. The M_r s ($\times 10^3$) of protein standards run in parallel are indicated.

Methods. Purified TNF (10 μ g) was radioiodinated by the iodogen method¹⁰. 0.1 M phosphate buffer (pH 7.4) was added to a glass tube coated with 5 μ g of iodogen (Pierce) and incubated with 1 mCi of Na ¹²⁵I for 10 min at 4 °C. Then the mixture was transferred to a tube containing TNF- α and allowed to react for 5 min at 4 °C. The reaction was stopped by removal of the soluble material which was separated from free iodide by filtration with Sephadex G-25 that had been equilibrated with 0.1 M phosphate buffer containing 0.1% gelatin. Sephadex G-25-purified material was characterized further on a Mono Q-column equilibrated in 25 mM Tris pH 7.4 containing 0.05% Tween 20 (b). Linear salt gradients of 0-0.25 M NaCl in equilibration buffer were used for elution of ¹²⁵I-TNF. The column was eluted at a flow rate of 1 ml min⁻¹ and 2 ml per fraction was collected. All these operations were carried out at room temperature. The column fractions were stored at 4 °C and analysed for radioactivity and cytolytic activity. The latter was measured by the lysis of actinomycin D-treated mouse fibroblast L929 cells (30,000 cells per microtitre well) plated in monolayer and quantitated by dye uptake⁷. The protein concentration of iodinated TNF was determined by immunoassay for TNF- α . Column fractions were also analysed by electrophoresis on 15% polyacrylamide slab gels¹⁷.

and - β share a common receptor and that the receptors can be up-regulated by interferon. Our results may explain previous observations regarding similar biological activities observed for these two cytotoxic proteins and also their synergistic action with interferons.

TNF- α and - β have been cloned and expressed by recombinant DNA methods in *Escherichia coli*. The proteins were purified to homogeneity from bacteria either by immunoaffinity purification using monoclonal antibodies or by ion-exchange chromatography as described previously¹⁻⁵. Both proteins were homogeneous by the criteria of amino-terminal sequence analysis and SDS-polyacrylamide gel electrophoresis. TNF- α and - β have relative molecular masses (M_r s) of 17,000 and 15,500, respectively, and specific activities of $\sim 100 \times 10^6$ units per mg as determined by lysis of actinomycin D-treated mouse L929 cells⁷.

The labelling of TNF- α and - β by chloramine-T, lactoperoxidase and Bolton-Hunter reagent methods provided ¹²⁵I-TNF with low specific activity and resulted in some cases in a >90% decline in biological activity. However, when TNF- α

Fig. 2 *a*, Time course of ^{125}I -TNF binding at 4 °C (○), 23 °C (●) and 37 °C (□) and *b*, competition curve of labelled bound TNF- α with unlabelled TNF- α . For each time point in *a*, 0.2×10^6 ME-180 cell monolayers were incubated in a final volume of 0.5 ml of McCoy's 5A medium containing 10% fetal bovine serum at the indicated temperature with 0.2×10^6 c.p.m. of ^{125}I -TNF- α in the presence and absence of 100 nM unlabelled TNF- α . Each data point represents the mean of triplicate determinations. After incubation, cell monolayers were washed three times with the incubation buffer, solubilized with 2% SDS and cell-bound radioactivity was determined in a γ -counter. In *b*, cells were incubated at 37 °C for 2 h with 0.2×10^6 c.p.m. of ^{125}I -TNF- α and indicated amounts of unlabelled TNF- α . Nonspecific binding was $\leq 10\%$ of total binding. The data are plotted as specific binding against concentration of unlabelled TNF- α . Inset, a Scatchard plot of the data.

was labelled by the iodogen method¹⁰, a fully biologically active ^{125}I -TNF- α was obtained which was stable for more than 4 weeks. ^{125}I -TNF- α had a specific activity of ~ 804 Ci per mmol protein, and $\sim 50\%$ incorporation of the label into the protein was observed. Approximately 50% of the TNF- α molecules were labelled, assuming monoiodination by this method. TNF- α contains seven tyrosine residues. Digestion of ^{125}I -TNF- α by trypsin (5% w/w) provided a single radioactive peptide. The amino-acid sequence of this peptide indicated that the tyrosine residue at position 87 was radiolabelled.

The product of this iodination reaction showed a single- M_r component of $\sim 17,000$ (TNF- α has a M_r of 17,100 as calculated from the protein sequence) when analysed by gel electrophoresis (Fig. 1a). Fractionation of ^{125}I -TNF- α by gel filtration chromatography on a TSK column also provided a single peak of radioactive protein which co-eluted with the biological activity (data not shown). The apparent M_r of labelled TNF- α by gel filtration was found to be $\sim 20,000$, similar to that determined for unlabelled recombinant TNF. A single peak of radioactive protein also co-eluted with biological activity when chromatographed by Mono Q-fast protein liquid chromatography (Fig. 1b), showing a retention time similar to that of unlabelled TNF.

We investigated the interaction of ^{125}I -TNF- α with cellular binding sites by incubating it with monolayers of human tumour cells in tissue culture. After incubation, the cells were washed three times with incubation medium, solubilized with 2% SDS and the radioactivity bound to the cell monolayer was measured. To avoid a species-specific barrier, human tumour cells were used to determine the binding of human TNF- α . It has been

Fig. 3 *a*, Competition of TNF- α , TNF- β and IFN- γ with ^{125}I -TNF- α for binding to ME-180 cells; *b*, competition of TNF- α with ^{125}I -TNF- α for binding to ME-180 cells before and after exposure to IFN- γ . Incubation conditions for *a* were as described for Fig. 2a, with the addition of the indicated concentrations of the following: TNF- α (●), TNF- β (○) and IFN- γ (□). The results are plotted as specific binding relative to an assay with no added competitor. In *b*, ME-180 monolayer cells were preincubated overnight in the absence (---) and presence (—) of $1 \mu\text{g ml}^{-1}$ of IFN- γ , then washed twice and examined for TNF- α binding as described for Fig. 2a. Inset, a Scatchard plot of the data.

reported previously that a human cervical carcinoma cell line, ME-180, is a very sensitive target for TNF², and we therefore used this cell line to study TNF binding in all experiments. All binding assays were carried out using a 0.5-ml total incubation volume layered on 0.2×10^6 cells plated as a monolayer. Binding was quite reproducible, each preparation of labelled TNF- α giving essentially the same results when tested in standard conditions over several weeks.

Figure 2a shows the time course of binding at 4, 23 and 37 °C. An initial increase in the rate of ^{125}I -TNF- α binding was observed with increase in temperature, reaching a plateau after 1 h, 2 h and 3 h at 37, 23 and 4 °C, respectively. The total binding was almost the same at all three temperatures. All subsequent experiments were carried out at 37 °C, the temperature of the cell cultures. The binding of ^{125}I -TNF- α to the cells was inhibited by various concentrations of unlabelled TNF- α ; Scatchard analysis of these data gave an apparent dissociation constant of 0.2 nM (Fig. 2b). The average number of binding sites per cell was $\sim 2,000$. These observations are consistent with the binding of ^{125}I -TNF- α to cellular receptors, although the identification of a specific receptor would require its characterization as a macromolecular complex with TNF and its purification.

Specificity of binding was examined by competition with highly purified recombinant preparations of TNF- β and IFN- γ . The competition with unlabelled TNF- β could be superimposed

on that obtained with TNF- α , whereas IFN- γ did not compete even at 1,000-fold excess concentration (Fig. 3a). It seems, therefore, that both TNF- α and - β compete with 125 I-TNF- α for binding to the same receptors.

It has been reported that IFN- γ is synergistic with TNF for anti-tumour action on many cell lines⁶⁻⁸. To understand the mechanism of this synergism, we pretreated the cells overnight with $1 \mu\text{g ml}^{-1}$ of IFN- γ and compared 125 I-TNF- α binding with untreated cells in a competition assay. Figure 3b shows the competition curve with IFN- γ -treated cells in relation to untreated cells in similar conditions. Scatchard analysis of the two curves indicated no significant change in the affinity constants, but a two to threefold increase in the number of receptors per cell was noted with interferon-treated cells. The increase in receptor number was observed consistently in four sets of experiments. Pretreatment of cells with $1 \mu\text{g ml}^{-1}$ of IFN- α was less effective than IFN- γ in inducing TNF receptors (data not shown).

Our experiments measured TNF binding at 37 °C. At this temperature, TNF may interact with cellular receptors in a complex way, possibly as a result of a series of metabolic events. This is suggested by our observation that the binding of 125 I-TNF after 2 h at 37 °C could not be reversed by either trypsin or salt and pH elution. However, a partial reversal (<30%) in binding was observed after 15 min (data not shown). At 4 °C, two-thirds of the total binding of 125 I-TNF could be reversed after 15 min. A similar kind of irreversible binding to that described here has been reported previously for receptors for platelet-derived growth factor¹¹. Furthermore, various characteristics of TNF binding reported here are very similar to those described for other polypeptide hormones including interferons¹¹⁻¹³. This includes a single class of specific high-affinity binding sites possessing a limited number of receptors per cell.

The inhibition of TNF- α binding by TNF- β may explain several common biological effects *in vitro* and *in vivo* observed for the two molecules⁸⁻¹⁴. Our experiments suggest that the receptor binding domains of TNF- α and - β should be similar. Two particularly conserved regions occur at amino acids 11-20 and 121-126 (TNF- α numbering) where all residues are homologous to TNF- β . It is possible that these regions of both proteins are involved in interaction with receptors. IFN- γ is known to exhibit synergistic biological effects with several other lymphokines including IFN- α , IFN- β , interleukin-2, TNF- α and - β (refs 7, 8, 15, 16). The mechanism of such synergistic action is unknown. This is the first report of an IFN- γ -induced increase in the total number of TNF receptors. It also suggests that the receptors are central to the action of TNF. Studies are now in progress to characterize TNF receptors further and to elucidate various biochemical events which follow receptor binding and precede cell death.

We thank Dr E. Rinderknecht's group for supplying highly purified preparations of recombinant DNA-derived TNF- α and - β for some of these studies, and Dr J. Ramachandran for critical reading of the manuscript. The assistance of Ms K. Harder in labelling of TNF and Mr H. Rodriguez for amino-acid sequence analysis is also appreciated.

Selective immortalization of murine macrophages from fresh bone marrow by a *raf/myc* recombinant murine retrovirus

Elisabetta Blasi, Bonnie J. Mathieson & Luigi Varesio*

Laboratory of Molecular Immunoregulation, National Cancer Institute, Frederick Cancer Research Facility, Building 560, Rm 31-71, Frederick, Maryland 21701, USA

John L. Cleveland, Patricia A. Borchert & Ulf R. Rapp

Laboratory of Viral Carcinogenesis, National Cancer Institute, Frederick Cancer Research Facility, Frederick, Maryland 21701, USA

Myeloid precursors can be grown *in vitro* in the presence of specific growth factors; however, their expansion is limited by a competing process of terminal differentiation^{1,2}. Proto-oncogenes seem to be involved in cellular proliferation and/or differentiation and may also play a role in the myelopoietic process^{3,4}. Murine myeloid precursors which are grown *in vitro* with growth factors respond with augmented self-renewal upon infection with recombinant retroviruses carrying the *v-myc* or *v-src* oncogenes⁵⁻¹¹, suggesting a synergism or complementation between some viral oncogenes (*v-onc*) and certain growth factors. We now show that the combination of two *v-onc* genes (*raf* and *myc*) induces the selective proliferation of monocytic cells from fresh murine bone marrow (BM) in the absence of a specific growth factor supplement. Depending on the culture conditions these cells can either differentiate and cease to proliferate or grow continuously, thus mimicking the alternative pathways that can be followed by committed BM stem cells *in vivo*.

Mononuclear BM cells obtained from femurs of C3H/HeJ mice were cultured in standard medium after overnight infection with retroviruses carrying *v-raf* and/or *v-myc* oncogenes. Untreated BM cells as well as cells infected with helper virus (Fig. 1a) or with retroviruses carrying only *v-raf* (3611, J1) or *v-myc* (J3, J5) (data not shown) died after a few days of culture. In contrast, in the cultures infected with the virus carrying both *v-raf* and *v-myc* (J2), clusters of non-adherent proliferating cells (J2-BM cells) could be detected 7-10 days after infection. J2-BM cells reached a peak in cell number and rate of proliferation 14 days after infection (Fig. 1a, b). At the same time, we observed a peak in frequency of colony-forming cells in soft agar (Fig. 1c). The decrease in cellular proliferation was not caused by lack of viral replication in J2-BM cells, since the fraction of virus-positive cells, as determined by infectious centre assay¹², was constant for at least 35 days following infection (Fig. 1d).

J2-BM cells growing in suspensions 14 days after infection (day 14 J2-BM cells) were characterized. Morphological examination of Giesma-stained cells revealed a relatively homogeneous cell population (Fig. 2a). The clonal expansion of day 14 J2-BM cells was further indicated by Southern blot analysis of J2-virus integration sites. The presence of a single virus-cell junction fragment (data not shown) in the DNA from the infected cultures strongly suggests that J2-BM cells are of clonal origin.

The monocytic nature of J2-BM cells was established by cytochemical and functional markers. J2-BM cells expressed nonspecific esterase, were phagocytic (Fig. 2b), and produced lysozyme ($\geq 8 \mu\text{g per } 10^5$ cells per 72 h). No peroxidase activity was detected. Flow cytometry analysis confirmed that J2-BM cells belong to the monocytic lineage (Table 1), since more than 95% were MAC-1-positive and 85% expressed Fc receptors. A minimum of 50% of the cells expressed the mouse heat-stable antigen, asialo-GM1, glycolipid and F4/80 antigen. In contrast, day 14 J2-BM cells were consistently negative for T-cell (Ly 1.1, Lyt 2.1, L3T4) and B-cell (surface immunoglobulins) markers.

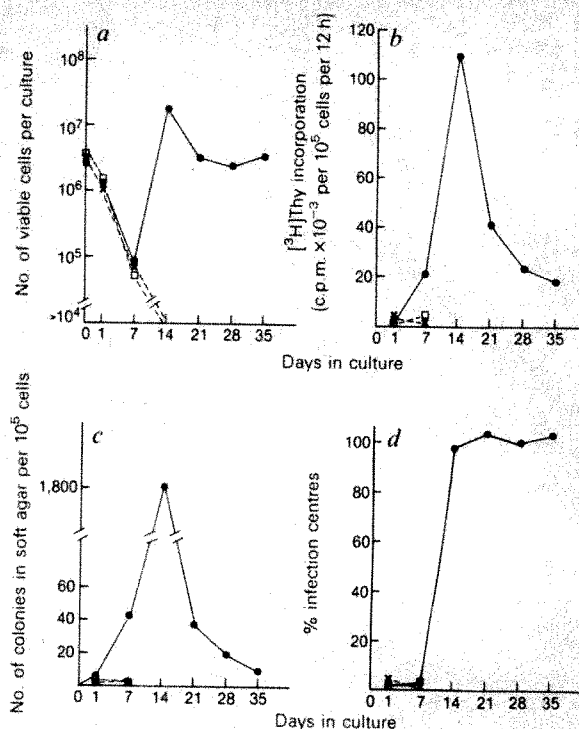

Day 14 J2-BM cells expressed helper and transforming virus-specific functions, being highly positive for production of trans-

Fig. 1 Kinetics of cell growth, ^3H -thymidine (^3H -Thy) incorporation, formation of colonies in soft agar, and % infectious centres in BM cells after infection. A leukaemogenic strain of Moloney murine leukaemia virus was used as helper virus. The results are from representative experiments. Cell growth (a), ^3H -Thy incorporation (b), formation of colonies in soft agar (c), and % infectious centres (d) were monitored weekly in uninfected controls (\square), and in BM cells infected with J2 virus plus helper virus (\bullet) or with helper virus alone (\times). Each point in b and c represents the mean of triplicate samples. The standard errors were less than 5% of the mean value.

Methods. The BM cells used in these studies were obtained from femurs of C3H/HeJ mice. This strain was used as a source of BM cells because their macrophages do not respond to endotoxins which often contaminate tissue culture media and stimulate endogenous production of growth factors in BM cultures¹⁹. 5×10^6 fresh BM cells, obtained by density separation on Ficoll²⁹, were resuspended in standard medium [Dulbecco's modified Eagle's medium supplemented with penicillin (100 units ml^{-1}), streptomycin (100 $\mu\text{g ml}^{-1}$), glutamine (4 mM) and 10% fetal bovine serum] and incubated overnight in the presence of control supernatants or of viruses containing supernatants. The viruses used were the following: (1) 3611 Moloney sarcoma virus³⁰ (containing *v-raf*); (2) J1 containing a complete *raf/mil* hybrid oncogene and the 5' half of MH2 *v-myc*^{31,32}; (3) J2 (which contains a complete *raf/mil* hybrid oncogene and a complete *myc* gene consisting of the 5' half of the MH2 *v-myc* and the 3' half of MC29 *v-myc*)^{30,31}; (4) J3 (derived from J2 by a 200-base pair deletion which takes the *raf/mil* gene out of the reading frame, *v-myc* remaining functional)³²; (5) J5 (which expresses a *v-myc* gene derived entirely from MC29)³².

The infections were performed at a viral concentration ranging from 1 to 5×10^4 particles per ml, as determined by fluorescence focus induction assay with anti-*v-myc*-antibodies³¹ in the case of *v-myc* carrying retroviruses J3 and J5, or by focus-forming assays in the case of *v-raf*-carrying viruses 3611 and J1. ^3H -Thy incorporation was determined in 10^5 cells pulsed with $10 \mu\text{Ci ml}^{-1}$ of [^3H]Thy (NEN) for 12 h at 37 °C. The cultures in soft agar were performed as described previously¹⁹ and the colonies (>50 cells) were scored after 10 days in culture. The infectious centres of mitomycin-treated BM cells were determined on 3T3 fibroblast indicator cells¹².

forming virus (Fig. 1d), for envelope glycoprotein gp70 (Table 1) and for *v-myc*- and *v-raf*-derived proteins. More than 90% of J2-BM cells, in fact, showed a specific nuclear staining (Fig. 2c) with anti-*v-myc* antibodies¹³ and a specific cytoplasmic fluorescence (Fig. 2d) with anti-*v-raf* antibodies¹⁴. Because of the cross-reactivity of the anti-*v-myc* or anti-*v-raf* antibodies with cellular *myc* or *raf* proteins, J2-BM cells were tested for expression of viral and cellular messenger RNA by Northern blot analysis and compared with normal or J2-virus-transformed NIH 3T3 fibroblasts. An MC29 *v-myc* DNA probe detected high levels of *v-myc* mRNA in both J2-BM cells and transformed

fibroblasts (Fig. 3a). Similarly, high expression of *v-raf* was detected using a cross-reacting human *c-raf* probe (Fig. 3b). When the blot was hybridized with a murine *c-myc* probe, which under these conditions does not recognize *v-myc*, no expression of *c-myc* was detected in J2-virus-transformed fibroblasts or J2-BM cells (Fig. 3c). These results show that J2-BM cells actively synthesized large amounts of viral *myc* and *raf* mRNA and that *c-myc* mRNA was undetectable. Therefore, the *myc* protein detected by immunofluorescence is probably of viral origin.

Infections of BM cells with J2 virus have consistently resulted

Cells (10^6 in 50 μl) were incubated for 40 min at 4 °C with 10–50 μl of appropriately diluted antibodies or with control supernatants. They were then washed three times and incubated for 40 min at 4 °C with 10 μl of appropriately diluted fluoresceinated anti-immunoglobulins (Cappel Laboratories). After another three washes the cells were analysed for immunofluorescence on a Cytofluorograf System 30-H with a 2150 computer (Ortho Diagnostic) capable of simultaneous measurement of forward and right-angle light scatter (488 nm), red (>600 nm) and green (530 nm) fluorescence. Cells were illuminated by a 4-W argon laser (Lexel) emitting 500 MW of 488-nm light. Cells analysed for immunofluorescence were selected by forward and right-angle light scatter. Dead cells less than 1% were identified by the uptake of propidium iodide (red fluorescence) and excluded from green fluorescence analysis. A green fluorescence histogram of 1,000-channel resolution was collected from 10,000 viable cells for each sample analysed. Both unstained cells and cells treated with fluorescent second antibodies were used as negative controls for these experiments.

* The designations of the antibodies used are indicated in parentheses.

† In parentheses are shown the relative mean fluorescence units measured on ~1.5 decade log scale with 1,000 channels of fluorescence.

‡ The high percentage of Fc receptor-bearing cells was also confirmed by enumeration of rosette-forming cells²¹ with IgG-coated red cells (data not shown).

§ These percentages represent the mean number of positive cells from three experiments. Although the net calculation of positive cells is ~50%, greater than 90% of the stained cells expressed a fluorescence intensity above the mean fluorescence of the negative controls.

Fig. 2 Photomicrographs of J2-BM cells. *a*, Morphology of Giesma-stained J2-BM cells; *b*, phagocytosis of opsonized zymosan by J2-BM cells 14 days after infection with J2 virus. *c*, *d*, Specific staining of *myc*- and *raf*-derived proteins in J2-BM cells 14 days after infection. Note nuclear fluorescence (*c*) and cytoplasmic fluorescence (*d*) in cells stained with anti-*myc* serum¹³ or anti-*raf* serum¹⁴, respectively.

Methods. For *a* and *b* 10^6 cells from a 2-week-old culture were incubated for 16 h in standard medium or in the presence of zymosan ($50 \mu\text{g ml}^{-1}$) opsonized with normal mouse serum. The cells were then washed and cytospin preparations were stained with Giesma. Cells which had ingested more than three zymosan particles were considered positive. For *c* and *d*, cytospin preparations of J2-BM cells were fixed in acetone for 10 min, stained for 40 min with anti-*myc* (provided by Dr Karin Moelling) or anti-*raf* sera, washed three times in phosphate-buffered saline (PBS), stained for an additional 40 min with appropriately diluted fluorescein-conjugated anti-rabbit serum (Cappel) and washed three times. Less than 1% of fresh BM cells showed very weak reactivity with either antibody, whereas J2-transformed fibroblasts displayed a pattern and intensity of fluorescence similar to that of J2-BM cells (data not shown). Slides were examined and photographed at 400- and 1,000-fold magnifications using a Zeiss microscope (made available by Dr U. Saffioti).

in selective growth of J2-BM cells at day 14. Following the initial proliferative phase associated with the presence of free floating clusters of cells (Fig. 4*a*), J2-BM cells formed an adherent monolayer (Fig. 4*b*) and ceased to proliferate. Adherent J2-BM cells were still virus producers, expressed *raf*- and *myc*-derived proteins and were morphologically indistinguishable from normal BM-derived macrophages (data not shown). Therefore, it appears that the proliferative stimulus of the J2 virus, which caused the *in vitro* expansion of the monocytic cells, is limited by a dominant differentiation process.

These considerations raised the question as to whether the differentiation was terminal, as in normal BM-derived macrophages, or whether J2-BM cells could revert to proliferating cells. We found that differentiated J2-BM cells could be induced to proliferate again by addition of dextran-based beads (CT; Cytodex, Pharmacia) to the 35-day cultures. Following addition of the beads, in four out of five experiments performed, the cells detached from plastic, became round and loosely adherent to the beads and formed floating cultures (Fig. 4*c*), which have been kept in continuous proliferation for more than 8 months.

J2-BM cells cultured with beads (J2-BM-CT cells) were clonable in soft agar (with an efficiency of 30–50%), indicating that their *in vitro* growth was an intrinsic property of individual cells rather than a proliferation mediated by the trophic activity of feeder cells. The plating efficiency of the J2-BM-CT cells, higher than that of the day 14 J2-BM cells (1.8%), could be the result of a progression step in the establishment of permanent cell lines from the initially infected cultures. Eighteen double-selected clones were tested for surface markers and found to be identical to each other (data not shown) and indistinguishable from the day 14 J2-BM cells (Table 1). Furthermore, all five clones tested so far produced transforming virus, suggesting that both oncogenes were active in the cloned cell lines.

Both *v-myc* and *v-raf* genes had to be expressed to induce proliferation of BM cells in standard medium, since viruses carrying either oncogene alone did not promote BM cell growth. The expression of both *v-myc* and *v-raf* therefore might have overridden the need for specific exogenous growth factor. This is consistent with earlier observations in the avian system where it was found that viruses carrying only *v-myc* augment the response of primary BM macrophages to growth factors^{9,10,16}. Moreover, in the murine system, infection of interleukin-3 (IL-3)-responsive BM cells with virus carrying *v-raf* induced their continuous *in vitro* proliferation¹⁷, whereas infection with virus carrying *v-myc* caused abrogation of IL-3 requirement¹⁸. It is possible that *v-myc* substitutes for growth factors in the prolifer-

Fig. 3 Northern hybridization analysis of J2-BM cells 14 days after infection (d14 J2BM) and of J2-transformed NIH 3T3 fibroblasts (3T3/J2). Polysome-associated RNA was isolated³³ and poly(A)⁺-containing RNA selected using oligo(dT)-cellulose chromatography. This RNA (15 μg) was denatured by glyoxalation³⁴, separated electrophoretically in agarose gels, transferred to nitrocellulose and hybridized under stringent conditions to ³²P-labelled nick-translated DNA probes¹⁵. *a*, *v-myc* hybridizations. The probe was a 1.4-kilobase (kb) *Pst*I/*Aha*III *v-myc*-specific fragment of the MC29 provirus^{35,36}. The intensity of hybridization with these RNAs varied considerably; the 3T3 and 3T3/J2 samples were exposed for 1 week whereas the d14 J2BM was exposed for 20 h. *b*, *raf* hybridizations. The probe was a 2.97-kb human *c-raf*-1 cDNA³⁷. The autoradiograph was exposed for 4 days. *c*, *c-myc* hybridizations. The probe was a 5.6-kb *c-myc* *Bam*HI fragment from subclone pS107 (ref. 38). The autoradiograph was exposed for 1 week. Sizes of RNAs were determined from their migration relative to that of ³²P-labelled denatured *Hind*III fragments of bacteriophage λ . The 7.6-kb RNA is the genome-size RNA of the J2 virus³²; several smaller subgenomic RNAs are also transcribed from this provirus. The 3.1-kb transcript is the endogenous *c-raf*-1 mRNA³⁹ whereas the 2.3-kb RNA is the *c-myc* transcript⁴⁰.

ation of J2-cells. In fact, we did not detect any colony-stimulating activity in virus-free supernatants from J2-BM-CT cells, as determined by standard colony-forming assay¹⁹ with either fresh mouse BM or day 14 J2-BM cells (data not shown).

Only J2-BM cells, but not normal macrophages, could be rescued from the resting differentiated stage and reverted to

Fig. 4 Photomicrographs of J2-BM cells maintained in liquid cultures. *a*, Morphology of day 14 J2-BM cells. *b*, Morphology of J2-BM cells 35 days after infection. *c*, Morphology of J2-BM cells maintained in active proliferation by culturing them with dextran-based beads. The cells were photographed *in situ* after gently removing most of the supernatants, at 160-fold magnifications using a Zeiss microscope.

proliferating cells by co-culture with beads, suggesting that the response to the growth-promoting activity of *v-raf* and *v-myc*, down-regulated by differentiation, could be reactivated. In our system, three signals seem to be required for immortalization, defined as continuous *in vitro* growth of J2-BM cells: the two oncogenes *v-myc/v-raf* and the beads. The mechanism underlying reversal of differentiation by addition of dextran-based beads is unclear. One possibility that we are testing is the absorption of differentiating factors onto their charged surface. Identification of factors involved in the induction of differentiation could provide insights into the cellular resistance to the transforming activity of oncogenes.

The interaction of steroids with their nuclear receptors induces a cascade of regulatory events that results from the activation of specific sets of genes by the hormone/receptor complex¹. Steroids, either acting alone or possibly synergistically with other growth factors, can influence the DNA synthesis and proliferation of specific target cells, initiate developmental pathways and activate expression of the differentiated phenotype²⁻⁷. Moreover, steroid hormones have been implicated in abnormal growth regulation both in tumours and tumour-derived cell lines^{8,9}. The identification of complementary DNAs encoding the human glucocorticoid receptor (hGR) predicts two protein forms (α and β ; 777 and 742 amino acids long, respectively) which differ at their carboxy termini¹⁰. We report here that both forms of the receptor are related, with respect to their domain structure, to the *v-erb-A* oncogene product of avian erythroblastosis virus (AEV), which suggests that steroid receptor genes and the *c-erb-A* proto-oncogene are derived

Fig. 1 Amino-acid sequence alignment of the carboxy-terminal half of the human glucocorticoid receptor (hGR) and *v-erb-A* oncogene product. Amino-acid residues 370-777 from hGR were aligned with amino-acid residues 1-398 from p75^{gag-erb-A}; identical residues are boxed and gaps are indicated by dashes. Matching cysteine residues are indicated by dots above the sequence.

from a common primordial regulatory gene. Therefore, oncogenicity by AEV may result, in part, from the inappropriate activity of a truncated steroid receptor or a related regulatory molecule encoded by *v-erb-A*. This suggests a mechanism by which *trans*-acting factors may facilitate transformation. We also identify a short region of hGR that is homologous with the *Drosophila* homoeotic proteins encoded by *Antennapedia* and *fushi tarazu*.

In the accompanying paper, we have deduced the entire amino-acid sequence of the human glucocorticoid receptor by nucleotide sequence analysis of overlapping cDNA clones¹⁰. The amino-acid sequence was scanned against a protein database maintained by R. Doolittle (University of California, San Diego) and a remarkable homology was found between the carboxy-terminal half of the receptor and the putative oncogene protein p75^{gag-erb-A} from AEV¹¹. Comparison of the last 387 amino acids of the receptor with the terminal 395 amino acids of the *gag-erb-A* fusion polypeptide revealed 85 matches, with 22% amino-acid identity overall (Fig. 1). The Needleman-Wunsch similarity value for the comparison was greater than 10 standard deviation units above the mean of 30 shuffled sequences, signifying statistically significant relatedness^{12,13}. In addition, 67 conservative amino-acid substitutions were found throughout this comparison interval. There is even greater identity (40%) between amino-acid residues 421 and 481, which corresponds to a cysteine/lysine/arginine-rich portion of the receptor. Nine out of ten cysteine residues of hGR are conserved in this region of maximal homology with *erb-A*. This is particularly significant because cysteines are not normally abundant and may participate in polypeptide tertiary structure.

In the amino-terminal half of the receptor there exist two short regions of homology with the homoeotic proteins encoded by the *Drosophila* genes *Antennapedia* (*Antp*) and *fushi tarazu* (*ftz*)^{14,15} (Fig. 2). The first region of homology (upper comparison in Fig. 2) is in the homoeo box region and the second (lower comparison in Fig. 2) precedes the homoeo box by eight amino acids. Although the match is limited, these polypeptide regions were selected from a database of 300,000 residues as the most significant matches using a comparison window of 18 amino-acid residues. The homoeo box is a 180-base pair (bp)

Fig. 2 Regional homology of the human glucocorticoid receptor with *Drosophila* homoeotic polypeptides. Numbers refer to the first amino-acid position in each protein segment of the *Antp* product¹⁴, the *ftz* product¹⁵, and hGR¹⁰. Broken lines indicate conservative amino-acid changes. Alignments were determined by a computer search of a database of 300,000 residues maintained by R. F. Doolittle, using an Inspect II program.

Fig. 3 Schematic representation of the primary amino-acid structure of the human glucocorticoid receptor, with the oncogene and homoeo box homologies indicated. The cysteine residues found in hGR¹⁰ are represented by arrows above the boxed coding region and basic amino acids (arginine and lysine) are denoted by solid circles. The immunogenic domain (IMM), determined from overlapping expression cDNA clones, the putative steroid-binding region (DEX) and DNA-binding domain (DNA) are indicated within the boxed receptor coding region. Numbers indicate amino-acid residues.

DNA sequence that is conserved in a variety of *Drosophila* homoeotic genes^{16,17}. These genes encode developmental regulatory proteins that appear to reside in the nucleus and thus, like the glucocorticoid receptor, appear to be *trans*-acting regulatory molecules^{18,19}. Whether these aspects of steroid receptor and homoeotic protein functions are reflected in structural relatedness awaits further investigation.

Structural analysis of the glucocorticoid receptor is required for understanding the mechanisms by which it regulates gene transcription. Here we attempt to construct a model for the hGR structure based on its primary amino-acid sequence¹⁰. Previous analyses of the rat receptor molecule have identified at least three domains which are physically separable by limited proteolytic cleavage²⁰⁻²². These include a major immunogenic domain, a steroid-binding region and a DNA-binding region. The immunogenic region resides on a proteolytic cleavage fragment of relative molecular mass (M_r) ~40,000 (40K), or 45% of the estimated receptor mass²⁰; the DNA- and steroid-binding domains are found on the remaining 55% of the molecule. Additional enzymatic cleavage studies localize the steroid-binding domain on a 22K peptide fragment containing no DNA-binding activity²³.

Expression cloning techniques^{10,24} were used to isolate three distinct but overlapping glucocorticoid receptor cDNA clones. The overlap between these clones indicates that boundaries for the immunogenic region occur between amino acids 145 and 278 (Fig. 3). Localizing the immunogenic domain at the amino terminus of the receptor indicates that the DNA-binding domain may be found in the carboxy-terminal half of the molecule. The steroid-binding region may be positioned more precisely by noting the properties of the variant human β -glucocorticoid receptor¹⁰. The β -hGR form differs from the α , or steroid-binding, receptor moiety in that the 50 carboxy-terminal amino acids of the α form are substituted by 15 amino acids in the β form¹⁰. As the *in vitro* translation product encoding the β -receptor fails to bind steroid¹⁰, the steroid-binding domain is localized at the extreme carboxy terminus.

Because the Cys-Lys-Arg-rich region (amino acids 421-481) embodies a particularly striking feature of the receptor and has

regions of homology with *v-erb-A*, we speculate that this region of the carboxy terminus may embrace the DNA-binding domain. It is interesting that the *Xenopus laevis* 5S RNA gene transcription factor TFIIIA²⁵⁻²⁷ contains a cysteine-rich region composed of nine repeated domains^{28,29}. The repeats are thought to be DNA-binding structures each containing a zinc ion at its centre. Although the hGR does not contain the large number of cysteines present in TFIIIA, the structural motif of a cysteine-rich region followed by basic amino acids is maintained. Accordingly, we propose a model for the receptor as shown in Fig. 3.

The two oncogenes *erb-A* and *erb-B*, encoded by AEV, are derived from cellular genes which comprise a multi-gene family in humans³⁰⁻³². The *erb-B* oncogene is a truncated form of the epidermal growth factor receptor and transforms erythroblasts, while *erb-A* strongly potentiates the effects of *erb-B* by blocking the maturation of erythroblasts at an early stage of differentiation³³⁻³⁸. Examination of the *v-erb-A* DNA sequence reveals that its amino terminus is synthesized as a fusion polypeptide with the viral *gag* product, while its carboxy-terminal 14 amino acids are derived from a combination of viral envelope and downstream *erb-B* sequences^{11,39}. Therefore, both the amino and carboxy termini of *v-erb-A* are apparently truncated relative to the cellular homologue.

The mechanism by which *v-erb-A* potentiates transformation is unknown, but the homology between *v-erb-A* and hGR suggests that the *erb-A* genes encode a family of transcriptional regulatory molecules. Assuming that the Cys-Lys-Arg-rich region of hGR represents the DNA-binding domain, then the region retained in *v-erb-A* might also bind specific DNA sequences. Thus, *v-erb-A* could exert its transformation effects by inappropriately stimulating gene expression in erythroblasts.

These results provide evidence for the relatedness of a family of proto-oncogenes to a known transcriptional regulatory protein, the glucocorticoid receptor. hGR also shows a discrete yet significant homology to the highly conserved amino acids in the homoeo box region of the *Drosophila* homoeotic genes *Antp* and *ftz*. This region is also found in the human genome, reinforcing the suggestion that the steroid receptor is composed of several functional domains. Localization of the immunogenic region in the hGR primary amino-acid sequence and the characterization of a variant receptor which does not bind steroid have permitted us to assign structural domains using experimental data gleaned from studies of the rat glucocorticoid receptor.

The unexpected indication from this study is that the steroid receptors and the *erb-A* proto-oncogenes share a primordial archetype. By analogy with the glucocorticoid receptor, these molecules may represent a new class of *trans*-acting factors that may be candidates for enhancer sequence binding proteins. Further characterization of the relationship of the glucocorticoid receptor to these oncogene products may elucidate the evolution of a family of eukaryotic transcriptional regulatory factors.

We thank Drs Kelly Mayo, Geoffrey Wahl, E. Brad Thompson and Michael Wilson for advice and discussion; R. F. Doolittle for computer analysis and many valuable discussions; and particularly Marijke ter Horst for preparation of artwork and secretarial assistance. This work is supported by grants from the NIH. R.M.E. and M.G.R. are Investigators of the Howard Hughes Medical Institute. C.W. is a Damon Runyon-Walter Winchell Cancer Fund Fellow (DRG-755) and S.M.H. is supported by a predoctoral training grant to the Department of Biology, University of California, San Diego.

Duchenne muscular dystrophy (DMD) is an X-linked recessive disorder which affects approximately 1 in 3,300 males, making it the most common of the neuromuscular dystrophies (see ref. 1 for review). The biochemical basis of the disease is unknown and as yet no effective treatment is available. A small number of females are also affected with the disease, and these have been found to carry X;autosome translocations^{2,3} involving variable autosomal sites but always with a breakpoint within band Xp21 of the X chromosome (implicated by other kinds of genetic evidence as the site of the DMD lesion⁴⁻⁶). In these female patients the normal X chromosome is preferentially inactivated, which it is assumed silences their one normal DMD gene, leading to expression of the disease. In one such affected female the autosomal breakpoint lies in the middle of the short arm of chromosome 21 (ref. 2), within a cluster of ribosomal RNA genes⁷. Here we have used rRNA sequences as probes to clone the region spanning the translocation breakpoint. A sequence derived from the X-chromosomal portion of the clone detects a restriction fragment length polymorphism (RFLP) which is closely linked to the DMD gene and uncovers chromosomal deletions in some male DMD patients.

The use of rDNA sequences as probes to identify the translocation junction was complicated by two factors. First, because the human genome contains 300-400 copies of the ribosomal gene distributed in 10 clusters on the five pairs of acrocentric chromosomes, the unique junction fragment would be difficult, if not impossible, to visualize on a Southern blot of total genomic

Fig. 1 Derivation of the translocation chromosomes der(X) and der(21). Below the der(X) chromosome is shown a schematic representation of the translocation chromosome at the breakpoint. The human ribosomal genes consist of a 43-kb unit repeated tandemly in blocks of 30–40 units on each of the 10 acrocentric chromosomes^{9,17}. The transcribed region is 13 kb long (represented as the solid black portion) and includes the 18S, 5.8S and 28S rRNA coding regions. The X-chromosomal portion of the translocation is represented by the stippled region, with the translocation breakpoint near the 3' end of the 28S gene. Below the schematic diagram are shown the subcloned regions BES, DSB, CEB, AXK and 100-3, used as probes.

Fig. 2 Identification of the X;21 junction fragment by Southern blotting. **a**, DNAs were isolated¹⁸ from cultures of hybrid A2 and mouse A9, digested with the restriction enzymes indicated, separated by electrophoresis on a horizontal 0.6% agarose gel and transferred to nitrocellulose¹⁹. The human-specific rDNA subclone 100-3 was ³²P-radiolabelled by nick-translation¹⁹. Prehybridization of nitrocellulose filters was at 50 °C in 50% formamide, 5 × SSPE (1 × SSPE = 0.18 M NaCl, 0.01 M sodium phosphate pH 7.4, 0.001 M EDTA), 5 × Denhardt's, 150 µg ml⁻¹ sheared salmon sperm DNA, 0.1% SDS. Hybridization was in the same solution plus 10% dextran sulphate and 3 × 10⁶ c.p.m. ml⁻¹ of radiolabelled DNA. The filter was washed in 0.1% SDS and 0.2 × SSPE several times at room temperature and twice at 65 °C for 30 min each. Autoradiography was at -70 °C with an intensifying screen for 6 days. The arrows indicate unique human-specific bands derived from the translocation breakpoint. The major bands in each track indicate fragments derived from the 3–4 normal rDNA repeat units found on this chromosome. **b**, Restriction map of the normal rDNA repeat unit¹⁰ and the translocation junction. The map of the translocation junction was derived from Southern blot analysis of hybrid A2 DNA probed with either AXK or 100-3. The probe binding sites are indicated at the top of the figure. Restriction sites: B, BamHI; N, NsiI; E, EcoRI; H, HindIII; P, PstI; and X, XbaI.

DNA from the patient. Second, the ribosomal gene repeat unit is 43 kilobases (kb) long so that any rDNA sequence selected as a probe would have a 50% chance of being over 20 kb from the translocation junction—too far to be useful for screening Southern blots or λ libraries of 15–20-kb fragments.

To overcome the first problem, we separated the translocation chromosomes from the human acrocentric chromosomes by segregation in somatic cell hybrids generated by fusion of the patient's fibroblasts to mouse A9 cells. Three useful hybrids were generated. Hybrids A2 and F1 carried only the derivative X translocation chromosome, der(X), containing most of the X chromosome joined at band p21 to the distal end of the short arm of chromosome 21 (Fig. 1). This translocation chromosome has been shown by Southern blot analysis to carry 3–5 copies of the rDNA gene⁷. The third hybrid, C2-T10, carried the reciprocal translocation chromosome, der(21), that is, most of chromosome 21 joined at band p12 (the rDNA gene cluster) to the distal end of Xp. This chromosome was shown to carry 40–60 copies of the rDNA gene⁴. DNA from hybrid A2 [der(X)] was used to identify the junction fragment (by Southern blot hybridization) and to construct the library from which the junction fragment was isolated.

To overcome the problem of the long rDNA repeat unit, it was necessary to use as probes a series of human-specific rDNA sequences spaced over the rDNA repeat unit. Southern blot analysis of hybrid A2 cell DNA cut with a variety of restriction enzymes and hybridized with probes BES, DSB and CEB (Fig. 1) was carried out in a search for a unique restriction fragment derived from the X;21 junction region. A unique BamHI fragment was revealed by the BES probe, but the presence of a similar fragment in all human DNA samples suggested that it was derived from the natural junction at the distal end of the rDNA block of chromosome 21 (DJ in Fig. 1). Further studies confirmed this notion and allowed the ribosomal gene complex to be oriented as shown in Fig. 1, with transcription in the telomere to centromere direction (R.G.W. *et al.*, manuscript in preparation). The X;21 junction was not revealed by these probes, which suggests that the junction must be near the 3' end of the 28S gene, the only region not adequately covered by the three probes. To examine that region in more detail, a 600-base pair (bp) XbaI–KpnI fragment (AXK, Fig. 1) was isolated from the transcribed spacer region. This probe, when hybridized to XbaI, PstI and HindIII digests of hybrid A2 cell DNA, revealed, in addition to the expected rDNA bands, additional unique bands at an intensity corresponding to one copy per cell⁸. This result allowed a map of the junction region to be constructed

with putative XbaI, PstI and HindIII sites located in X-chromosomal DNA (Fig. 2).

Using this information, numerous attempts were made to clone the translocation junction using AXK as a probe. These experiments included construction of both phage and plasmid libraries from either partial digests of hybrid DNA or size-selected DNA fragments isolated by agarose gel electrophoresis. None of these cloning attempts yielded the junction fragment, forcing the conclusion that either ribosomal sequences or X-chromosomal sequences from this region were refractory to cloning. The former possibility seemed most likely as previous experiments had suggested that clones carrying the transcribed spacer region and 28S gene were underrepresented in total genomic libraries⁹. In order to isolate a human-specific probe much closer to the translocation breakpoint, the human 28S ribosomal gene sequence¹⁰ was compared with the homologous mouse sequence¹¹. Three human-specific regions were identified, subcloned and used to probe Southern blots of genomic DNA from the hybrid cell line. The results obtained for one of these probes (100-3) are shown in Fig. 2a. In addition to the restriction fragments previously identified with AXK, several new bands were visualized, including a 12-kb BamHI fragment containing the translocation breakpoint, which carried at most 1.8 kb of rDNA. To clone the junction fragment, DNA from the A2 hybrid line was cut with BamHI and size-selected fragments of 11–15 kb were cloned into λ Charon 35 (ref. 12).

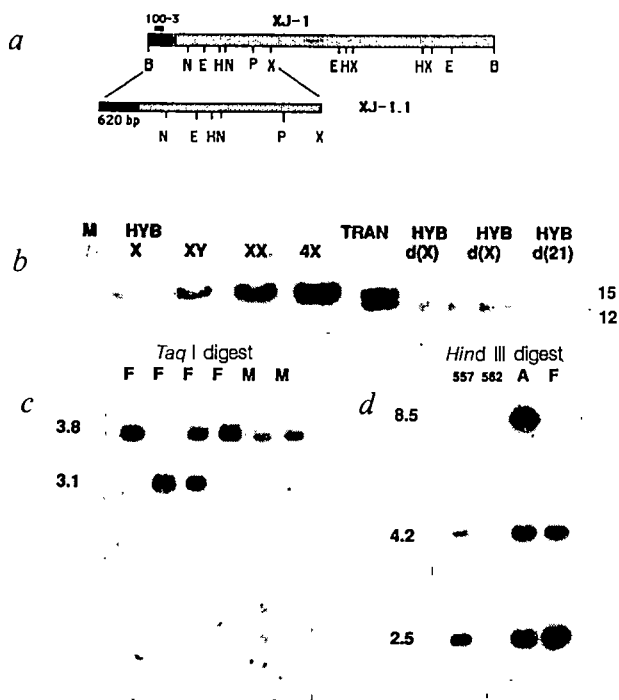

Fig. 3 *a*, Restriction map of the translocation junction clone XJ-1. The stippled area represents X-chromosomal material. The solid region represents that part derived from the rDNA cluster on chromosome 21. The translocation breakpoint is 620 bp from the 5' *Bam*HI site (unpublished data). The 100-3 probe binding site is indicated above the figure. The XJ-1.1 subclone from which the 1-kb *Nsi* fragment was derived is indicated below the map. The restriction site designation is described in Fig. 2. *b*, Localization of XJ-1 to the X chromosome. A Southern blot of total genomic DNA from several cell lines was probed with the 1-kb *Nsi*I fragment derived from XJ-1.1. The lanes contain 5 μ g of *Bam*HI-digested DNA from: M, mouse A9; HYBX, AHA 11a, an X-only mouse/human hybrid; XY, normal male; XX, normal female; 4X, a human female line with four X chromosomes; TRAN, the X;21 translocation patient; HYB d(X), the A2 and F1 hybrid lines carrying the der(X) chromosome; HYB d(21), the C2-T10 hybrid carrying the der(21) chromosome. The normal X chromosomes generate a 15-kb *Bam*HI fragment (lanes 2-5); the patient (lane 6) has a normal 15-kb band and a 12-kb translocation band; the hybrids carrying only the der(X) translocation chromosome (lanes 7, 8) have only the 12-kb band. *c*, A *Taq*I polymorphism associated with XJ-1.1. DNAs from four unrelated females (F) and two males (M) were digested with *Taq*I, electrophoresed, blotted and hybridized to the 1-kb *Nsi*I fragment from clone XJ-1.1 as described in Fig. 2 legend. The probe hybridizes to a 3.8- and a 3.1-kb fragment in females heterozygous for the RFLP (lane 3) and to either a 3.8- or a 3.1-kb band in homozygous females (lanes 1,2 and 4) and males (lanes 5, 6). *d*, Analysis of deletions for XJ-1.1 in males with DMD. DNAs from two unrelated males with DMD (557 and 562), the translocation patient (A) and her father (F) were digested with *Hind*III and probed with the *Nsi* fragment from XJ-1.1. Of the 50 DMD males tested in this manner, 49 had the normal banding pattern as seen with patient 557, that is, a 4.2- and a 2.5-kb band. One patient (562) showed no hybridizing sequences, indicating a deletion of this part of the chromosome. The translocation patient (A) shows a complex pattern consisting of a 4.2- and a 2.5-kb band derived from her normal X chromosome plus a 4.2- and an 8.5-kb band from her translocation chromosome. Her father (F) shows a normal banding pattern.

Approximately 10^6 recombinant phage were plated on *Escherichia coli* DB1161 (recA⁻recBC⁻sbcB⁻)¹³ and screened with 100-3, yielding five positive clones. Restriction mapping of these clones revealed all five to be identical. The map of the insert of one of these phage (XJ-1) is shown in Fig. 3a. The cloned fragment contained all of the restriction sites revealed by Southern blotting, consistent with its being the junction fragment. To further establish its identity as the junction fragment, a 1-kb *Nsi*I fragment, free of repeat sequences, was isolated from a *Bam*HI-*Xba*I subclone (XJ-1.1) and used to probe Southern blots of *Bam*HI-digested DNA from genomes with one, two or four human X chromosomes. The results (Fig. 3b) reveal a hybridization signal proportional to the number of human X chromosomes. This fragment also hybridized

Table 1 Linkage of XJ-1.1 to DMD

Rec., recombinant.

to a mouse-human hybrid carrying an X chromosome as the only human chromosome (Fig. 3b) and to one carrying only the short arm of the X chromosome (not shown). The hybridization pattern is also consistent with a translocation junction origin. In Fig. 3b, the *Nsi*I fragment of XJ-1.1 reveals a 15-kb *Bam*HI fragment from a normal X chromosome, a 12-kb band (that is, the cloned portion) from hybrid A2 with the der(X) translocation chromosome, and a double band from the patient's DNA, reflecting her two X chromosomes. A similar heterozygotic pattern in the patient's DNA was revealed with eight other restriction enzymes tested.

To show that the translocation junction is closely linked to the DMD locus, two studies were done. First, the *Nsi*I fragment of XJ-1.1 was used to seek RFLPs by probing Southern blots of DNA from four unrelated females cleaved with 27 restriction enzymes. A polymorphism detected with *Taq*I (Fig. 3c) was used to examine segregation patterns in several DMD families. Of 83 females in these families, 23 were heterozygous for the *Taq*I RFLP and no recombinants were found between XJ-1.1 and DMD in 16 meiotic events (Table 1). Of these 16 meiotic events there were 3 of known phase and 13 of unknown phase. All results were obtained with affected or normal sons of obligate DMD heterozygous carriers. A LOD score was calculated¹⁴ based on segregation of the *Taq*I RFLP in these DMD families and yielded a maximum of 3.4 at $\theta = 0$ centimorgans. The sample size of 16 meiotic events used in this analysis is quite small and many more informative families will be required to give a more precise estimate of linkage distance.

The second approach was to test a set of 50 DMD patients for deletion or rearrangement of the XJ-1.1 region. One of the 50 males (patient 562) displayed no hybridizing sequences (Fig. 3d), indicating deletion of the XJ-1.1 region. Recently, Kunkel *et al.*¹⁵ have isolated a probe (pERT87) closely linked to DMD which maps distal to XJ-1 and have detected deletions in 5 of 57 unselected DMD patients¹⁶. We have probed Southern blots (provided by Dr L. Kunkel) of DNA from all of these patients and found that all five also show deletions of XJ-1.1. Conversely, our panel of 50 DMD patients was screened by Kunkel for hybridization to pERT87. Only one patient, 562, failed to show hybridization to this probe (Kunkel, personal communication). The fact that these deletions are thought to be quite small (250-600 kb) suggests that XJ-1.1 and the probes described by Monaco *et al.*¹⁶ are closely linked to each other and to the DMD locus.

The underlying assumption in this work is that the translocation event disrupted the DMD locus, causing expression of the disease. Thus the junction clone or clones derived from chromosome walking should make it possible to find RNA transcripts from this region and eventually identify the gene product itself.

At a more immediate level, the translocation fragment will provide new RFLPs for use in carrier detection and prenatal diagnosis of DMD. This new RFLP will complement existing Xp21 probes and together with those described recently by Monaco *et al.*¹⁶ should provide enough closely linked markers to allow accurate diagnosis of most potential carriers.

We thank Dr H. F. Willard for AHA 11a DNA; Dr A. R. Wyman for *E. coli* strain DB1161; Dr L. M. Kunkel for providing

pERT87 probes, Southern blots of several DMD deletion patients and unpublished results from his laboratory; and Dr I. L. Andrulis for helpful discussions. Some of the earlier attempts at cloning the junction region involved significant effort on the part of Drs L.-C. Tsui, H. F. Willard and J. D. Freisen, whom we thank for their contributions. This work was supported by grants from the MRC of Canada (to R.G.W., P.N.R., and M.W.T.); the Muscular Dystrophy Association of Canada (to R.G.W., P.N.R. and M.W.T.); the Muscular Dystrophy Association, USA (to R.G.W.) and the NIH (to R.D.S.).

An intron in the 23S ribosomal RNA gene of the archaeobacterium *Desulfurococcus mobilis*

Jørgen Kjems & Roger A. Garrett

Biostructural Chemistry, Kemisk Institut, Aarhus Universitet, DK-8000 Aarhus C, Denmark

The archaeobacteria have been defined, at a molecular level, as constituting a third primary kingdom consisting of the methanogens, the extreme halophiles, and the sulphur-dependent extreme thermophiles. In reaching this conclusion, Woese and colleagues used the 16S ribosomal RNA as an approximate chronometer for evolutionary time and demonstrated that, at a nucleotide sequence level, the archaeobacteria are as different from the eubacteria and eukaryotes as the latter kingdoms are from one another^{1,2}. Current research on archaeobacteria is yielding valuable insights into the evolutionary relationships between archaeobacteria, eubacteria and eukaryotes, and into the early forms of cellular life³. Here, we extend this knowledge by providing the first evidence for the occurrence of an intron within any prokaryotic ribosomal RNA. The intron was found within the 23S rRNA gene of the sulphur-dependent and anaerobic Thermoproteale *Desulfurococcus mobilis*, which was isolated from hot acidic springs in Iceland at temperatures up to 97 °C^{4,5}. The intron contains 622 base pairs (bp); it is very A + T-rich (65%) compared with the 23S rRNA gene (34%), and it exhibits a large open reading frame. The splicing site occurs in domain IV of the 23S RNA at a position close to that of an intron of the lower eukaryote *Physarum polycephalum*⁶; the intron does not readily fall into one of the three classes of eukaryotic nuclear introns because it has features in common with those of classes I (rRNA) and III (transfer RNA)⁷.

23S rRNA genes from two archaeobacteria, the extreme thermophile *D. mobilis* and the extreme halophile *Halococcus morrhuae*, have recently been sequenced in this laboratory, and both exhibit sequence and secondary structural features that are

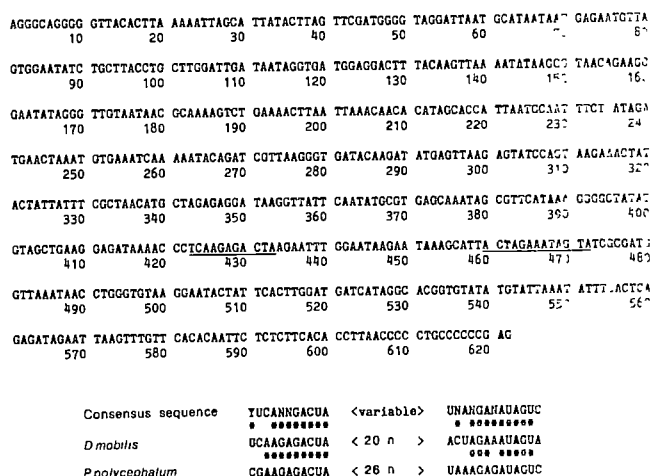

Fig. 1 Nucleotide sequence of the 622-bp intron, showing the strand corresponding to the transcribed RNA. The consensus sequences that may be required for the splicing of the eukaryotic rRNA introns are underlined in the sequence, and they are aligned below it (see text). The sequence was determined as follows. A 4-kilobase *Bam*HI fragment, subcloned into M13mp18, was digested with restriction enzymes specific for 4 bp. The DNA fragments were fractionated on a 4% polyacrylamide gel and cloned into M13mp18 or mp19 in both directions. Their directions were determined by 'figure 8' mapping²⁶. Single-stranded DNA was prepared and used as a template for DNA sequencing by the dideoxynucleotide method⁸, using [α -³²S]ATP (1,000 Ci mmol⁻¹; Amersham); the DNA was run on sequencing gels containing 4-6% polyacrylamide and salt or wedge-shaped gradients²⁷. Both DNA strands are sequenced, at least twice, and overlaps were obtained at each restriction site. Some differences were observed between our restriction map of the 23S rRNA gene and that published by Neumann *et al.*⁹. Some of the restriction enzyme cuts that we found were reported by Neumann *et al.* only for the closely related *D. mucosus* rRNA operon, and our estimate of the 16S-23S RNA spacer region was larger. However, we agree that the 5S RNA and 23S RNA genes are uncoupled, which is an exclusive property of the *D. mobilis* operon⁹.

exclusive to the archaeobacteria (H. Leffers, J.K. and R.A.G., unpublished work). These sequences were aligned with those of other eubacterial and eukaryotic 23S-like rRNA genes and the *D. mobilis* gene was shown to contain a large 622-bp insert. Its nucleotide sequence is given in Fig. 1.

To establish whether the insert was, indeed, an intron, the 23S RNA was sequenced over the putative splicing site using reverse transcriptase. A 5' end-labelled restriction fragment was used as a primer with purified 23S RNA as the template; sequences were obtained using dideoxynucleotides⁸. Figure 2 shows an alignment of the resulting complementary DNA sequence with that of the 23S RNA gene. The result demonstrates that the insert was excised from the pre-rRNA and thereby establishes both the nature and location of the intron.

Southern hybridization studies between the purified large rRNAs and total chromosomal DNA confirmed the result of Neumann *et al.*⁹ that only one operon exists for the large rRNAs (data not shown). There can be little doubt, therefore, that this gene is both transcribed and spliced. This view, that it is not a pseudogene, was reinforced by demonstrating that 300 nucleotides of cDNA, sequenced around the splicing site (Fig. 2) and the 5' end of the 23S RNA, were identical to the gene sequence.

The intron is located within the functionally important domain IV of the 23S-like RNAs¹⁰ (Fig. 3). The sequence shown is that of *D. mobilis*, while the numbering system and secondary structure are based on *Escherichia coli* 23S RNA¹¹. The uncertainty in the assignment of the splicing site, at nucleotide 1,953 (± 1), is due to an A-G direct repeat occurring at the exon-intron junctions. The insert is flanked by highly conserved sequences that contain several post-transcriptionally modified nucleotides in *E. coli*¹⁰ (Fig. 3) and at least one in *D. mobilis* 23S RNA

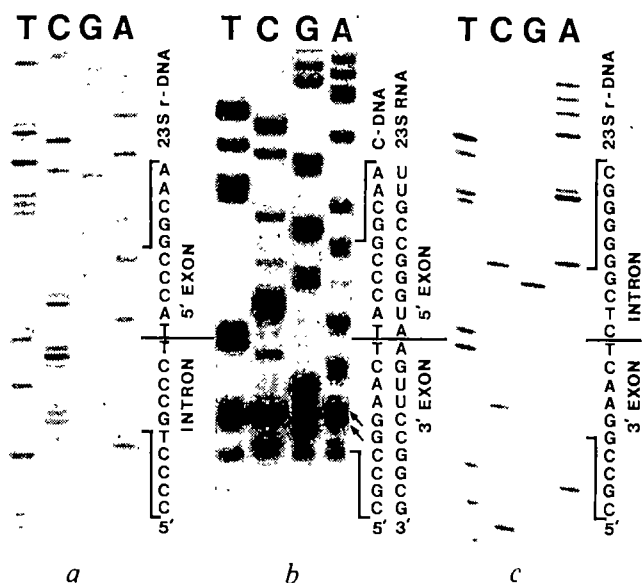

Fig. 2 Gel *b*, sequencing gel showing the sequence of cDNA obtained through the splicing site using reverse transcriptase. This gel is flanked by DNA sequencing gels showing the 5' (*a*) and 3' exon-intron junctions (*c*). Over 200 nucleotides of the cDNA sequence were read and they corresponded exactly to the gene sequence.

Methods. The gene sequence was determined by hybridizing 3 pmol of a double-stranded *HhaI*-*HaeIII* restriction fragment, which had been 5' end-labelled using [γ - 32 P]ATP (6,000 Ci mmol $^{-1}$; ICN Pharmaceuticals), to 5 pmol 23S RNA. The hybridization reaction was performed in 15 μ l buffer (20 mM HEPES pH 7.0, 0.4 M NaCl, 1 mM EDTA, 89% formamide) by heating at 95 $^{\circ}$ C for 2 min, then at 55 $^{\circ}$ C for 90 min, and cooling quickly. Sequencing reactions were performed in 10 μ l buffer (50 mM Tris-HCl pH 8.3, 10 mM MgCl $_2$ and 2 mM dithiothreitol) containing 200 μ M dNTP, 200 μ M of the appropriate dideoxy dNTP, 0.5 pmol primer template complex and 10 units AMV reverse transcriptase (Life Sciences, Florida). cDNA was fractionated on 6% polyacrylamide gels (20 cm \times 40 cm \times 0.02 cm). Strong termination of nonspecific nature was detected in the cDNA track at G 1,960; this may result from a modification of G 1,959.

(Fig. 2). Chemical modification studies have also indicated that part of this region is accessible on ribosomes of both eubacteria and eukaryotes 11 . Each of these characteristics (sequence conservation, post transcriptional modification and location on the ribosomal surface) is a strong indicator of a functionally important region of RNA, although no definite function has yet been established 10 .

It appears to be a general property of rRNA (and tRNA) introns that they are clustered in functionally important regions. Two rRNA introns have been located in neighbouring positions of domain IV: one occurs in the *P. polycephalum* gene at position 1,949, which is 3–5 nucleotides 5' of the present intron 6 , and another occurs in *Tetrahymena pigmentosa* at position 1,925 (ref. 12) (Fig. 3). Most of the others have been located in a region of domain V that has been strongly implicated in the peptidyl transfer reaction 11 . The function(s) of the introns remains unclear. The splicing reaction could be a mechanism for activating ribosomes after assembly 13 ; it could also constitute a proofreading for the correct assembly of important functional sites.

Eukaryotic nuclear introns have been divided into three groups on the basis of their splicing mechanisms: (1) rRNA; (II) mRNA and (III) tRNA 7 . In order to classify the present intron, we aligned its sequence with the 501-nucleotide intron that occurs at an adjacent position in the 23S-like rDNA of *P. polycephalum* 6 . Two common sequences were detected at similar relative positions (Fig. 1). They correspond to the consensus sequences of class I introns that are essential for correct

Fig. 3 Secondary structure of a major part of domain IV of the pre-23S RNA of *D. mobilis*. The numbering system and the secondary structure derive from that of *E. coli* 23S RNA 11 . The ringed nucleotides are highly conserved in 12 sequenced 23S-like RNAs from eubacteria, archaeobacteria, chloroplasts and the eukaryotic cytoplasm 10 . Domain IV of *E. coli* 23S RNA 11 contains several modified nucleotides and these are indicated by asterisks. *D. mobilis* exhibits at least one modification, at G 1,959 (see Fig. 2). The three pairs of arrows indicate the three possible splicing junctions, and the putative helix at the start of the intron is shown. P.p. intron, the position of the *P. polycephalum* intron 2 (ref. 6).

splicing $^{14-16}$. Other properties, however, are not shared by class I introns; these include the putative base pairing between the ends of the RNA (Fig. 3), the lack of internal core structure, and the absence of a uridine at the 3' end of the 5' exon 14,15,17 . The latter are characteristics of class III introns that occur in the anticodon loops of nuclear tRNAs; these exhibit no obvious consensus sequences and the splicing reaction is probably directed by an endonuclease recognizing invariant features of the tRNA structure 18,19 .

Large open reading frames (ORFs) are common to the transcribed introns of many mitochondrial mRNAs, some large rRNAs and chloroplast tRNAs 15,20 . As illustrated in Fig. 4, the intron in *D. mobilis* also contains one ORF that starts 57(\pm 1) nucleotides from the 5' exon-intron junction, continues through

Fig. 4 The locations of stop codons in the three reading frames of the RNA that is transcribed from the intron and the flanking region of the 23S RNA gene. ORF denotes the open reading frame. The plot was obtained using a Staden computer program 28 .

the 3' junction and extends 215 (± 1) nucleotides into the 3' exon. The likelihood that it codes for a protein is reinforced by the fact that the other frames of the intron contain 28 and 30 stop codons. Moreover, two putative Shine-Dalgarno sequences (5' AGGA 3' and 5' GGGGT 3') precede the ORF; these lie 3 and 7 nucleotides, respectively, from the start codon and both can interact with the sequence 5' ACCTCCT 3' at the 3' end of the 16S RNA (data not shown). Furthermore, a 30-nucleotide region preceding these putative Shine-Dalgarno sequences is very A+T-rich (80%); this feature is common to ORFs of introns in the rRNA genes of *Neurospora crassa*²¹. The extension of the ORF by 215 (± 1) nucleotides into the 3' exon suggests either that it is translated prior to splicing or that the RNA circularizes after splicing, as was found for intron II of *T. pigmentosa*²², such that translation is terminated by stop codons upstream from the initiation codon.

In conclusion, this is the first intron to be found in a rRNA gene of any prokaryotic system. The result complements those introns found in archaeobacterial tRNAs, that is, the small putative introns in tRNA^{Leu} and tRNA^{Ser} of *Sulfolobus solfataricus*²³ and a 105-bp intron in the tRNA^{Trp} gene of *Halobacterium volcanii*²⁴; all exhibit important differences compared with their eukaryotic counterparts. Collectively, though, these results reinforce the view that the archaeobacteria, in general, share more characteristics with the eukaryotes than do the eubacteria, where an intron has been reported only for the thymidylate synthase gene of the phage T4²⁵.

We thank Professor Wolfram Zillig for providing *D. mobilis* cells and Dr Wilhelm Ansorge for advice on gel systems for

DNA sequencing. We thank Henrik Leffers and Niels Larsen for advice and help with the sequence alignments and Lisbeth Heilesen for her assistance with the manuscript. The research was supported by grants from the Danish Natural Science Research Council.

Near-reciprocal phenotypes caused by inactivation or indiscriminate expression of the *Drosophila* segmentation gene *ftz*

Gary Struhl

Department of Biochemistry and Molecular Biology,
Harvard University, 7 Divinity Avenue,
Cambridge, Massachusetts 02138, USA

Early in development, *Drosophila* embryos express the segmentation gene *fushi tarazu* (*ftz*)^{1,2} in a 'zebra' pattern of active and inactive stripes, each about the width of a segment primordium³. If the *ftz* gene is prevented from functioning, alternating portions of the body normally derived from the active stripes fail to develop, resulting in larvae which lack the denticle bands normally formed by the mesothorax and odd-numbered abdominal segments (that is, thoracic segment T2 and abdominal segments A1, A3, A5 and A7). Here, using the *Drosophila* heat shock protein 70 (*hsp70*) gene promoter⁴⁻⁷ to drive widespread expression of *ftz* transcripts on heat shock, I find that unrestricted *ftz* activity can cause a reciprocal 'pair-rule' phenotype—that is, the absence of the denticle bands which are normally derived from segments T1, T3, A2, A4, A6 and A8. These results show that both the 'on' and 'off' states of *ftz* gene expression have instructive roles in the development of alternating regions of the body, and hence suggest that the *ftz* gene acts combinatorially with other pair-rule genes (for example, *even-skipped*, *odd-skipped*, *paired*)⁸⁻¹⁰ to establish the metameric pattern of the body.

To examine the consequences of indiscriminate *ftz* expression, a sequence coding for most of the mature *ftz* messenger RNA (including the entire open reading frame of the *ftz* protein)¹¹ was fused to the promoter of the *hsp70* gene⁵⁻⁷, and this hybrid gene was incorporated into the germ line by P-element-mediated transformation^{12,13} (see Fig. 1). Four independent transformant lines were obtained: two, called HSF2 and HSF3, have been examined in detail. The HSF2 and HSF3 transformants result from insertions of a single copy of the *P(hsp70-ftz, Adh⁺)*

element into chromosomes 2 and 3, respectively (segregation and Southern blotting data not shown): in both cases, animals homozygous for the transduced element are viable and fertile.

The *hsp70* promoter can be induced by heat shock throughout the life cycle except for the first few hours of embryogenesis (up to the blastoderm stage, ~2.5-3.5 h after egg laying, 25 °C) and the late stages of oogenesis^{5-7,14}. Both HSF transformants expressed the *hsp70-ftz* hybrid transcript in response to heat shock during the blastoderm stage as well as in older embryos (see, for example, Fig. 2). When HSF embryos were heat-shocked during the blastoderm stage, approximately half of the resulting larvae displayed pair-rule phenotypes (described below and in Fig. 3). Similar segmentation phenotypes were not observed when HSF embryos were exposed to heat shock after the blastoderm stage, nor were they observed when control embryos lacking the *hsp70-ftz* hybrid gene were heat-shocked at any time during embryogenesis.

Previous studies have shown that almost all cells of the body induce the *hsp70* promoter on heat shock⁵⁻⁷. Because wild-type embryos normally display a tightly restricted zebra pattern of *ftz* transcripts during the blastoderm stage, the altered segment patterns caused by heat-shocking HSF embryos during this period probably result from ectopic expression of the *hsp70-ftz* transcripts.

Before describing the HSF phenotypes, it is helpful to consider the pair-rule phenotype caused by apparent null mutations in the *ftz* gene. *ftz*⁻ embryos develop into larvae which appear to delete every other segment^{1,2} (that is, segments T2, A1, A3, A5 and A7; see Fig. 3*b, c*). This assessment is based primarily on the presence or absence of conspicuous belts of ventral hairs (denticle bands) which are formed by anterior portions of each segment. However, examination of sensory organs such as Keilin's organs, which are positioned at or near the anteroposterior compartment boundary¹⁵, as well as the patterns of dorsal hairs, which display segment-specific differences in both anterior and posterior compartments of several segments^{15,16}, indicates that the deleted regions are composed of segment-length domains which begin and end near the anteroposterior compartment boundaries within adjacent segments (Fig. 3; see also refs 9, 10). Note that the regions deleted

Fig. 1 Composition of the *hsp70-ftz* fusion gene (a) and generation of germline transformants (b). a, The fusion gene is composed of three pieces: (1) a 450-base pair (bp) sequence containing the *hsp70* promoter (hatched bar), (2) a composite *ftz* gene which contains the uninterrupted open reading frame present in the mature *ftz* transcript (solid bar), and (3) a 150-bp fragment of the 3' end of a *Xenopus* β -globin complementary DNA including a 23-bp poly(A) tail (open bar). The *hsp70* (132E3) and globin fragments are described in refs 33 and 34; the composite *ftz* gene was generated by substituting a 580-bp region of the genomic clone *Dm437* (ref. 35) containing the single *ftz* intervening sequence, with the corresponding 400-bp region of the cDNA clone *G20*⁺ (ref. 11) as shown (X, A, S, B, Sp and P represent, respectively, the *Xba*I, *Ava*II, *Sal*I, *Bgl*II, *Sph*I and *Pst*I sites; indicates that the fragments are joined by blunt-end ligation) (see ref. 11 for the *ftz* cDNA and genomic sequences). The 5' portion of the fusion gene transcript (arrow) consists of 200 bp of the 5'-untranslated *hsp70* transcript joined by a 10-bp linker sequence (L = AAGCTTGGGC) to the *ftz* gene about 80 bp in front of the start of the major open reading frame (AUG). The 3' end of the fusion gene, beginning at the end of the open reading frame (UAG), consists of ~400 bp of the *ftz* 3'-untranslated region, the putative polyadenylation signal (AATAAA), and the next 100 bp of the *ftz* genomic sequence. b, The *hsp70-ftz* fusion gene was inserted into the P-element transformation vector pPA-1 (J. Posakony, unpublished) which carries the *Adh* (alcohol dehydrogenase) gene as a selectable marker. The directions of transcription of the *hsp70-ftz* and *Adh* genes are indicated by arrows; P, sites for P-factor-mediated integration. Germline transformants were then generated in *Adh*^{fr6} *cn*; *ry* hosts by standard means^{12,13}. The same hosts were used as untransformed controls for the heat-shock experiments.

in *ftz*⁻ embryos cannot be precisely demarcated, partly because of the lack of sufficient cuticular landmarks, but also because they are somewhat variable in extent (see Fig. 3 legend). Also, a small proportion of *ftz*⁻ embryos (usually <20%) show more extreme segmental fusions in which the denticle bands associated with one or more additional segments appear to be partially or completely deleted.

In contrast to *ftz*⁻ embryos, HSF2 and HSF3 embryos heat-shocked during the blastoderm stage can give rise to abnormal larvae which partially or completely lack the denticle bands normally formed by segments T1, T3, A2, A4, A6 and A8—exactly those denticle bands which are retained in *ftz*⁻ embryos (see, for example, Fig. 3). Thus, conditional, and presumably unrestricted, expression of the *hsp70-ftz* hybrid gene can cause a pair-rule phenotype which is superficially reciprocal to that resulting from absence of the *ftz* gene.

Both the frequency and extents of these reciprocal phenotypes are variable, perhaps because an extreme phenotype results only when the embryos are heat-shocked during a brief, optimal period during the blastoderm stage (for example, late enough for the *hsp70* promoter to be fully inducible, but early enough to allow sufficient *ftz* gene product to accumulate before it has to act). This variability has the fortunate consequence that a broad range of phenotypes can be examined. As in the case of

Fig. 2 Heat-shock control of the *hsp70-ftz* fusion transcript. The presence of normal *ftz* and hybrid *hsp70-ftz* transcripts was assayed by Northern blot analysis using a probe complementary to the composite *ftz* gene (solid bar in Fig. 1a). a, HSF2 embryos aged 2 3/4–3 1/4 h after egg laying express the normal *ftz* transcript (~2.0 kilobases (kb))^{11,35,36} and, at a low concentration, the 2.2-kb hybrid *hsp70-ftz* transcript (not visible in this exposure). b, HSF2 embryos of a similar age to those in a, but heat-shocked for 20 min, express the 2.0-kb *ftz* transcript as well as a series of larger transcripts, including a discrete 2.2-kb transcript: the 2.2-kb transcript almost certainly corresponds to the *hsp70-ftz* transcript (which should be ~200 bp longer than the normal *ftz* transcript if terminated near the putative polyadenylation signal), and the larger transcripts may correspond to hybrid transcripts which terminate farther downstream. Note that the *hsp70-ftz* transcripts are less abundant than the native *ftz* transcripts; this difference may be due to poor induction of the fusion gene in some embryos (consistent with the finding that only about half of the HSF embryos heat-shocked during this period give rise to larvae showing reciprocal *ftz* phenotypes). It may also indicate that the levels of ectopic *hsp70-ftz* transcripts necessary to alter the segment pattern may be lower than the levels of *ftz* transcripts normally expressed in the zebra pattern. c, Control embryos (6–10 h after egg laying) heat-shocked for 20 min express low levels of the normal *ftz* transcript. d, HSF2 embryos of a similar age to those in c, but heat-shocked, express low levels of the normal *ftz* transcript as well as high levels of the fusion transcripts.

Methods. Embryos were grown at 25 °C and heat-shocked at 35 °C for 20 min. Northern blot analysis was performed as described previously³⁷ (~8–10 μ g of total nucleic acid was loaded per lane). The *ftz* probe was generated by gel extracting and then nick-translating of the composite *ftz* gene. Neighbouring lanes loaded with RNA from 2 3/4–3 1/4-h-old HSF2 embryos were probed with sequences complementary to the major actin transcripts (1.7, 1.95 and 2.2 kb)³⁸, providing size markers for the *ftz* and *hsp70-ftz* transcripts. Similar results were obtained using HSF3 embryos. Low levels of an additional 1.75-kb transcript were detected in all four lanes; whether this represents a *bona fide ftz* transcript is unknown.

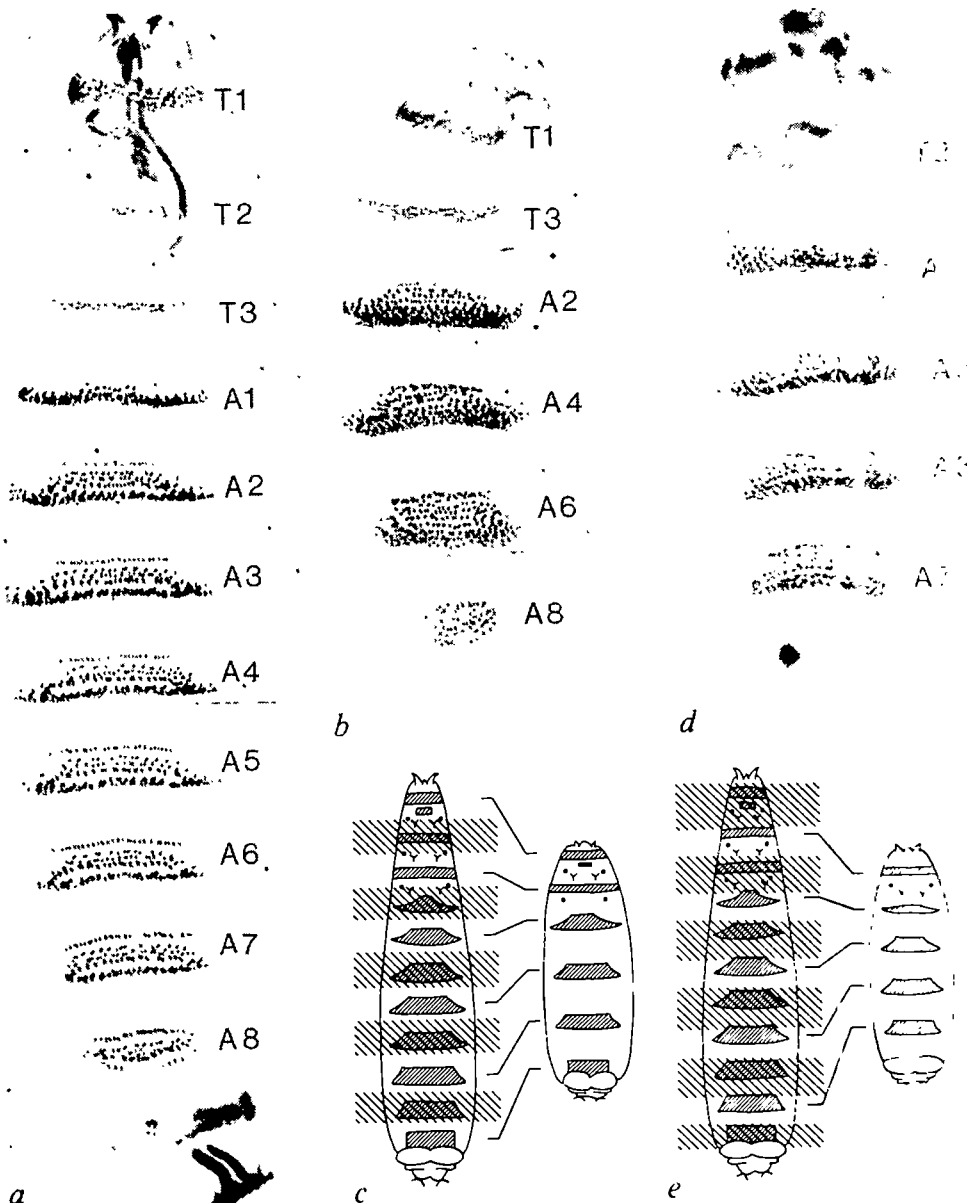

ftz⁻ embryos, there seems to be no absolute boundary between deleted and retained regions; however, the deletion pattern shown in Fig. 3e illustrates the boundaries which are usually respected. Note that the deletion patterns of *ftz*⁻ and heat-shocked HSF larvae are not perfectly reciprocal, but appear to overlap to some extent (Fig. 4).

The *ftz* gene is one of about 10 'pair-rule' genes that, when mutant, cause the apparent deletion or fusion of homologous portions of every other segment^{8–10}. Moreover, each of these genes is associated with a particular deletion pattern, suggesting that they are responsible for the development of overlapping, but different, repeating intervals of the segment pattern^{8–10}. The spatial distributions of transcripts of two pair-rule genes, *ftz* and *hairy* (*h*), have been determined; both are expressed in zebra patterns in which the active stripes correspond approximately to the regions of the body that are deleted in mutant embryos^{3,17}. The emerging picture therefore seems to be that the deletion patterns associated with the different pair-rule genes define alternating regions of the body where these genes are both expressed and required for normal development. Why then are the *ftz* and *h* genes (and possibly the remaining pair-rule genes) silent in the reciprocal portions of the body where their activities seem to be dispensable?

The results presented here argue strongly that the *ftz* gene is

Fig. 3 Near-reciprocal pair-rule phenotypes of *ftz*⁻ and heat-shocked HSF embryos. **a**, Wild-type first-instar larva. The three thoracic and first eight abdominal segments (T1-T3, A1-A8) each bear a characteristic band of ventral hairs (denticles) formed by the anterior compartment, **b**, **c**, *ftz*⁻ larva (homozygous for an apparent null allele, *ftz*⁹⁰⁹³; ref. 39). As described in the text, mutant larvae form only half the number of denticle bands (those belonging to segments T1, T3, A2, A4, A6 and A8)^{1,2} and hence appear to lack every other segment. In fact, the deleted regions are not segments, but rather segment-length units which begin close to the anteroposterior compartment boundary in one segment and end close to the boundary within the next segment. This is particularly clear in the thoracic segments because: (1) the patterns of dorsal and ventral hairs in each 'double segment' are composites of the anterior (a) and posterior (p) portions of adjacent segments (that is, T1a+T2p, T3a+A1p, A2a+A3p, etc.), (2) two sets of lateral sensory hairs⁴⁰ are often formed in each 'double segment' (normally each segment has a single set positioned just anterior to the compartment boundary within the segment), suggesting that a region slightly less than a segment's length lying between the lateral hairs in adjacent segments has been deleted, and (3) partial or complete Keilin's organs (which normally lie on or near the anteroposterior compartment boundary in each thoracic segment¹⁷) are usually present in the T1aT2p double segment, but are present only rarely in the T3aA1p double segment (deletion of a segment-length unit beginning and ending around the compartment boundaries within adjacent segments might be expected to leave behind partial or complete Keilin's organs more frequently when both segments are thoracic than when one is thoracic and the other abdominal). The exact boundaries between deleted and retained portions of the body seem to vary somewhat. For example, Keilin's organs are composed of three sensory hairs, two derived from the anterior compartment and a third derived from the posterior compartment¹⁵. In the T1aT2p double segment of *ftz*⁻ embryos, the Keilin's organs are sometimes rudimentary di-hairs or mono-hairs, or are absent. A further aspect of the *ftz*⁻ phenotypes is that some pattern elements, such as specific sensory hairs or rows of denticles, appear to be duplicated in each metameric unit¹. One consequence of this phenomenon, which has also been observed with mutations in other pair-rule genes¹⁸, is that the denticle bands appear broader than in wild-type embryos. **d**, **e**, Heat-shocked HSF3 larva. In contrast to *ftz*⁻ larvae, HSF larvae derived from embryos heat-shocked during the blastoderm stage often partially or completely lack the denticle bands associated with segments T1, T3, A2, A4, A6 and A8. Partial deletions often appear as fusions which join the denticle bands of particular pairs of segments (T1+T2, T3+A1, A2+A3, etc.). In progressively more extreme deletions, the denticle bands belonging to the more anterior segments (T1, T3, A2, etc.) appear progressively narrower or are eliminated, leaving the denticle band derived from the more posterior segments (T2, A1, A3 etc.) largely intact (as in **d**). Thus, the deleted regions seem to be slightly larger than segment-length units which begin and end just outside the boundaries of segments T1, T3, A2, A4, A6 and A8. As in the case of *ftz*⁻ embryos, the limits of the deletion pattern illustrated in **e** seem to define the usual stopping line, but some embryos show more extreme deletion phenotypes. Because of the variation in phenotype, these limits should be considered provisional. **a**, **b**, **d**, Dark-field photomicrographs (ventral aspects, positive images; $\times 120$). **c**, **e**, The regions deleted from the normal pattern (after ref. 8). The denticle bands are shaded and the missing regions indicated by hatched bars; Keilin's organs and ventral pits are shown as Y and o symbols, respectively. Keilin's organs are found only rarely in the T3aA1p double segment of *ftz*⁻ larvae and are therefore not indicated in this position in **c**. No attempt has been made to map the deleted regions anterior to T1 or posterior to the A8 denticle band, though some portions of these terminal regions fail to develop in each case.

Methods. **d**, **e**, Embryos were collected and allowed to develop at 25°C and were usually heat-shocked for 20 min at 35°C, although shocks of 5 or 10 min were also effective at generating reciprocal *ftz* phenotypes. Typically, 500-1,000 fertilized eggs were collected during a 30-min period and shocked between 2 and 3 h after egg laying. In these conditions, ~50% of the resulting larvae showed partial or complete deletions of the denticle bands of at least three alternating segments; fewer than 1% of the embryos heat-shocked between 3 $\frac{1}{4}$ and 3 $\frac{3}{4}$ h after egg laying (or at any time thereafter) developed into larvae showing reciprocal *ftz* phenotypes. HSF2 and HSF3 embryos responded similarly to heat shock.

normally silent in the 'off' stripes because it must be off to allow these regions to develop. Thus, the alternating on and off stripes of *ftz* activity seem to be equally critical, in their respective domains, for organizing the metameric pattern of the body. Similar evidence is not yet available for the *h* gene. However, dosage studies of another pair-rule gene, *run*^{8,18}, have shown that extra wild-type copies can cause pair-rule deletions which are nearly reciprocal to the deletions resulting from loss of gene function (ref. 10 and J. P. Gergen and E. Wieschaus, personal communication). Though the interpretation is less clear in this

case, it is possible that these 'anti-run' phenotypes are caused by elevated levels of *run* expression in regions where the gene must normally be either silent or expressed at a low level.

These results can be explained by positing that the pair-rule genes act combinatorially to initiate the development of repeating portions of the segment pattern (see also ref. 10). For example, each cell along the anteroposterior axis of the blastoderm may express a specific combination of pair-rule genes (perhaps in response to a periodic spatial cue). This combination of genes then initiates the development of a specific interval of

Fig. 4 Overlap between the *ftz*⁻ and heat-shocked HSF pair-rule phenotypes. The regions of the body deleted in heat-shocked HSF larvae (Fig. 3e) are largely anterior to the regions deleted in *ftz*⁻ larvae (Fig. 3c). Note that the deletion patterns are not perfectly reciprocal: regions of common overlap (heavy shading) and common exclusion (unshaded) are found in alternating intervals along the body.

the repeat pattern, perhaps by activating the correct patterns of expression of other genes such as *engrailed*^{8,19-22} and the segment polarity genes^{8,9} which function subsequently to control growth and cell pattern within segments. Accordingly, both the on and off states of pair-rule gene function would have equal instructive roles because the developmental behaviour of any given cell or region would depend on the initial code-word of on and off pair-rule genes. In this regard, pair-rule genes may be acting in a manner functionally analogous to that of homoeotic genes of the bithorax and *Antennapedia* complexes²³⁻³¹.

Though this interpretation is prompted in part by the reciprocal nature of the *ftz*⁻ and heat-shocked HSF phenotypes, it should be noted, as shown in Fig. 4, that these phenotypes are not perfectly reciprocal: some regions of the body are deleted in both *ftz*⁻ and heat-shocked HSF larvae while other regions appear unaffected in either case. Regions of overlap between the two deletion patterns suggest that *ftz* and perhaps other pair-rule genes do not function simply as binary switches, but rather that differences in relative levels of their gene products, or perhaps temporal sequences of alternating expression, may also be important in defining specific portions of the segment pattern. Note that the stripes of cells expressing *ftz* transcripts narrow towards the end of the blastoderm stage^{3,32}, indicating that the gene may be on to different extents, or first on and then off, in some cells of each stripe.

I thank Matthew Scott, Hugh Pelham, Paul Krieg, Christiane Nusslein-Volhard and Jim Posakony for making their cloned genes, cloning vectors and mutations freely available; Paul Macdonald for help with constructing the *hsp70-ftz* hybrid gene; Janice Fischer for generating the germline transformants by microinjection; and Doug Melton for catalysing the initial phases of this work. I also thank Peter Lawrence and Peter Gergen for their critical comments on the manuscript, Tom Maniatis for allowing me to work in his laboratory and Harvard University and the USNIH (program project grant NIH 5 PO1 GM29301) for financial support.

Simian virus 40-mediated *cis* induction of the *Xenopus* β -globin DNase I hypersensitive site

Tariq Enver*, Alison C. Brewer & Roger K. Patient

Department of Biophysics, King's College London,
26-29 Drury Lane, London WC2B 5RL, UK

Regions in chromatin which are hypersensitive to the action of DNase I appear to be associated with sites of genetic activity; the association between DNase I hypersensitivity and transcriptional activation is well known¹. In the case of the chicken β -globin gene the establishment of a DNase I hypersensitive site is dependent on tissue-specific *trans*-acting factors^{2,3}. Such factors have also been implicated in the action of viral and cellular enhancers⁴⁻¹⁰, which are themselves hypersensitive to DNase I¹¹⁻¹⁴. Enhancers have been defined operationally as DNA sequences which act in *cis* to potentiate transcription from their own, heterologous or cryptic promoters. This activity is essentially unaffected by changes in the orientation, position (5' or 3') or distance of the enhancer element with respect to its cognate promoter (ref. 15 for review). We demonstrate here that the transcriptional rescue of the *Xenopus laevis* β -globin gene by simian virus 40 (SV40) sequences including the enhancer coincides with the conferment of DNase I hypersensitivity upon that gene, and that this occurs in the absence of any change in the complement of *trans*-acting factors. These results suggest that a propensity to form sites hypersensitive to the action of DNase I is encoded in the primary sequence of DNA¹⁶, and that this predilection is aggravated by SV40 sequences, perhaps through a mechanism dependent on supercoiling.

Neither human nor rabbit β -globin genes are expressed when they are introduced by transfection into HeLa cells on plasmid vectors in a transient assay, but transcription of these genes is restored by linkage in *cis* to the SV40 enhancer^{17,18}. We have examined the behaviour of the *X. laevis* β_1 -globin gene in similar conditions. HeLa cells were transfected with recombinant plasmids and left for 48 h, after which both nuclei and total cytoplasmic RNA were prepared. The RNA was analysed for the presence of correctly initiated globin transcripts by quantitative S₁

* Present address: Division of Medical Genetics, University of Washington, Seattle, Washington 98195, USA.

Fig. 1 The SV40-*Xenopus* β_1 -globin gene construct, pJYM β_1 . pXG β_1 (ref. 28) contains a 3.5-kilobase *EcoRI* *X. laevis* β_1 -globin gene fragment cloned into the *EcoRI* site of pAT153 (ref. 29). pJYM Δ RB was made by ligating the large *EcoRI*/*Bam*HI fragment containing all the early and part of the late transcription units of SV40 to an *EcoRI*/*Bam*HI fragment from pBR322 from which sequences poisoning replication in eukaryotic cells had been deleted³⁰. The *EcoRI* fragment containing the 3.5-kb β_1 -globin gene from pXG β_1 was then inserted into the unique *EcoRI* site of pJYM Δ RB to produce pJYM β_1 . The open box represents SV40-derived sequences. The thick line represents *X. laevis*-derived sequences. The thin line represents plasmid sequences. Arrows indicate the direction of e (early), l (late) and β_1 (globin) transcription. Approximate locations of DNase I hypersensitive sites A, B and C (Fig. 3) are arrowed. P is the 5' end-labelled *Bcl*I/*Rsa*I *S*₁ mapping probe. Q is the *Bgl*II/*Nco*I probe used for hypersensitive site mapping. ORI marks the approximate location of the SV40 origin.

nuclease mapping with the following results. When introduced alone (pXG β_1 ; Fig. 1 legend), the *X. laevis* β_1 -globin gene was not expressed (Fig. 2a, lane 6). Expression was not rescued by using DNA templates prepared from strains of *Escherichia coli* deficient in methylation (Fig. 2a, lane 7). However, when the gene was inserted into plasmid pJYM Δ RB (Fig. 1 legend), containing SV40 sequences, the resultant recombinant, pJYM β_1 (Fig. 1), produced high levels of β_1 -globin gene transcription (Fig. 2a, lane 5). The pattern of transcription obtained from pJYM β_1 was identical to that seen when RNA isolated from *X. laevis* erythroblasts was mapped using *S*₁ nuclease (Fig. 2a, lane 2). Furthermore, globin-specific RNA isolated from pJYM β_1 -transfected HeLa cells co-migrated on Northern blots with β_1 -globin messenger from *Xenopus* erythrocytes. Therefore, like the rabbit β -globin gene transcripts¹⁷, transcripts from the *X. laevis* β_1 -globin gene are correctly processed in HeLa cells.

Transcription could not be restored by co-transfecting pJYM Δ RB and pXG β_1 (Fig. 2b, lane 3), thereby demonstrating that it is not a result of the action in *trans* of SV40 early gene products. HeLa cells are semi-permissive for SV40¹⁹, and thus allow large-T-antigen-dependent replication of DNAs containing functional SV40 origins. Both pJYM Δ RB and pJYM β_1 produce large-T antigen as judged by immunofluorescence (data not shown), and have intact SV40 origins, thereby allowing them to replicate. pXG β_1 , on the other hand, is devoid of both the SV40 origin and early region. Although we have not formally excluded the possibility that transcriptional rescue is a result of replication, other workers¹⁷ have demonstrated that the enhancer-mediated potentiation of gene transcription is independent of this effect. We therefore consider it likely that the enhancer element in pJYM β_1 is involved in stimulating the expression of the *X. laevis* β_1 -globin gene.

Fig. 2 Analysis of β_1 -globin gene expression in HeLa cells. Total cytoplasmic RNA isolated from HeLa cells 48 h after transfection was analysed for *X. laevis* globin-specific transcription by either *S*₁ nuclease mapping^{31,32}, followed by electrophoresis on denaturing polyacrylamide gels³³ (a, b), or Northern blotting (c). The size marker, M in a and b, is a 3'-end-labelled pAT153 *Hpa*II digest yielding fragment sizes of: 634 (faint), 494 (faint), 407 (faint), 244, 240, 219, 205, 192, 162 (doublet), 149, 124, 112, 92, 78, 69, 36 and 28 base pairs (bp). a, Lane 1, 190-bp *Bcl*I/*Rsa*I fragment used as *S*₁ probe (P in Fig. 1). Lane 2, 225 ng of total cytoplasmic RNA from X.1. erythroblasts. The arrow indicates the protected fragment size for authentic globin mRNA. Lane 3, a Maxam and Gilbert sequencing reaction size marker. Lane 4, pJYM Δ RB. Lane 5, pJYM β_1 . Lane 6, pXG β_1 . Lane 7, pXG β_1 grown in a *dam*⁻ strain of *E. coli*. The arrow indicates the protected fragment size for authentic β -globin mRNA. c, Lane 1, pJYM Δ RB. Lane 2, pJYM β_1 . Lane 3, pXG β_1 . Lane 4, pXG β_1 *dam*⁻. Lane 5, 225 ng of total cytoplasmic RNA from X.1. erythroblasts. The arrow indicates the size of processed *X. laevis* β_1 -globin mRNA. **Methods.** Transfection and RNA preparation: HeLa cells were transfected by the DEAE-dextran procedure essentially as described elsewhere³⁵ with the following modifications: (1) after removal of the DNA/DEAE-dextran mixture, cells were 'hocked' with 5 ml of phosphate-buffered saline containing 1% glycerol for 1 min; and (2) cells were not treated with chloroquine diphosphate after transfection. After 48 h, the cells were lysed as described in Fig. 3 legend, and total cytoplasmic RNA was prepared as described elsewhere³⁶ and run on neutral agarose gels. Ribosomal RNA profiles were used to evaluate RNA concentration and integrity. *S*₁ nuclease analysis: The *Bcl*I/*Rsa*I fragment (P in Fig. 1) of the *X. laevis* β_1 -globin gene was 5'-end-labelled with ³²P to a specific activity of 1×10^7 c.p.m. per pmol of 5' ends, strand separated on denaturing polyacrylamide gels and electroeluted. Cytoplasmic RNA (15 μ g) isolated from transfected HeLa cells was hybridized to 2×10^5 c.p.m. of probe (probe excess) as described elsewhere³⁷, and digested with *S*₁ nuclease as described previously³² except that the concentration of Zn²⁺ was increased by a factor of 10 to compensate for the high level of EDTA in the hybridization buffer. Northern analysis: Cytoplasmic RNA (15 μ g) isolated from transfected HeLa cells was electrophoresed on a formaldehyde/agarose gel, transferred to nitrocellulose³⁸ and hybridized with a nick-translated³⁹ *Xenopus* β_1 -globin cDNA clone pXG8D2⁴⁰ as described previously¹⁴.

As DNA transfected into cultured cells has been shown to form chromatin²⁰, we compared the chromatin structure of the transcriptionally active globin gene in pJYM β_1 with that of the quiescent copy in pXG β_1 . Given the close correlation between DNase I hypersensitivity and transcriptional activity¹, we chose DNase I as a structural probe. Nuclei from transfected cells were treated with differing concentrations of DNase I, after which total DNA was prepared and analysed by indirect end labelling²¹. This analysis revealed three hypersensitive sites in pJYM β_1 , designated A, B and C (Fig. 3). Site A maps to the late side of the SV40 control region and probably corresponds to the reported DNase I hypersensitivity of the enhancer element itself^{14,20}. Site B occurs in the SV40 late coding region between the initiation codons for viral capsid proteins VP2 and VP3. This site has not been described previously, although the data of Jongstra *et al.*²² reveal a hypersensitive band in the same region. Site C occurs in the 5' region of the *X. laevis* β_1 -globin gene extending roughly from -100 to +50 relative to the start of transcription at +1. This agrees quite closely with the position of the hypersensitive site associated with the *X. laevis* β_1 -globin gene in *Xenopus* erythrocytes (ref. 23 and J. Allan, unpublished). None of these sites is observed when naked DNAs are subjected to DNase I (M. E. Walmsley *et al.*, in preparation).

Note that when no DNase I was added, pJYM β_1 was specifically cleaved by an endogenous nuclease (Fig. 3, lane 6). It can be seen that the three DNase I hypersensitive sites form only a small subset of the regions recognized by the endogenous nuclease. The endogenous cleavage pattern may reflect some other feature of chromatin structure; alternatively, these bands may be the products of cleavage of naked DNA molecules with a marked sequence specificity, a possibility now being investigated in our laboratory. DNase I analysis of nuclei from HeLa cells transfected with pXG β_1 revealed no hypersensitive sites (Fig. 3, lanes 1-5); this was not due to a failure of DNase I, whose activity was confirmed by the reduction in size of HeLa cell genomic DNA as judged by ethidium bromide staining (data not shown).

The concomitant rescue of *Xenopus* β_1 -globin transcription and the induction of hypersensitivity seen in pJYM β_1 was also achieved in another construct, pJYM $\beta_1\Delta 1p$ (Fig. 4). In this construct the late promoter region of SV40 has been deleted, excluding the possibility that the results obtained with pJYM β_1 were due to activation of the globin unit by 'readthrough' late transcription. Furthermore, the orientation of the *Xenopus* β_1 -globin gene relative to the viral early control region has been changed in pJYM $\beta_1\Delta 1p$, reinforcing the long-range nature of the process(es) involved. This could be taken as evidence for a causative role for the SV40 enhancer, which is known to act essentially independently of orientation and distance. However, like pJYM β_1 , pJYM $\beta_1\Delta 1p$ can replicate in HeLa cells. We have not excluded a possible role for replication, whose effects are also relatively position independent, in the activation of the *Xenopus* β_1 gene.

The results presented here reinforce the already strong correlation between DNase I hypersensitivity and transcriptional activity¹. Their novelty resides in the fact that a DNase I hypersensitive site is established by changing the sequence environment of a gene without any concomitant alteration in the complement of cellular *trans*-acting factors. It is unlikely that DNase I hypersensitivity is merely a consequence of transcription, for in a chicken erythroid cell line, DNase I hypersensitivity of the β -globin gene precedes its transcriptional activation²⁴. Our results are particularly pertinent given the association between the binding of *trans*-acting factors and hypersensitivity¹⁵, together with the demonstration that the reconstitution *in vitro* of the chicken globin gene DNase I hypersensitive site is dependent on development- and tissue-specific factors^{2,3}. Weintraub, however, has proposed¹⁶ that the nuclease-hypersensitive 5' and 3' regulatory regions of eukaryotic genes have the potential to form an altered DNA secondary structure, and that this ability is contained within the DNA sequence alone. He demonstrated

Fig. 3 Indirect end-labelling analysis of DNase I-treated transfected material. Nuclei were prepared from transfected HeLa cells after 48 h and treated with DNase I. Total DNA was then restricted with *Bgl*II and hybridized with a *Bgl*II/*Nco*I probe (Q in Fig. 1). The linear main band is marked 'lin' and hypersensitive sub-bands are arrowed A, B and C. Lanes 1-5 represent nuclei from cells transfected with pXG β_1 treated with 0, 1, 2, 5 and 8 $\mu\text{g ml}^{-1}$ DNase I (Worthington) respectively. Lanes 6-10 represent the same concentration course performed on nuclei from cells transfected with pJYM β_1 .

Methods. Trypsinized HeLa cells from a confluent 250-ml flask were washed once in RPMI 1640 medium containing 20 mM HEPES, resuspended in 0.72 ml of ice-cold lysis mix (50% glycerol, 50 mM Tris 7.9, 100 mM KCl, 5 mM MgCl₂, 0.05% saponin and 200 mM β -mercaptoethanol) and left on ice for 10 min. The lysed mixture was spun at 5,500 r.p.m. for 15 min at -5°C in a Sorvall HB4 fitted with Eppendorf tube adaptors. The supernatant was removed for RNA preparation and the nuclear pellet was resuspended in 0.8 ml of ice-cold buffer A (100 mM NaCl, 50 mM Tris pH 8.0, 3 mM MgCl₂, 0.1 mM phenylmethylsulphonyl fluoride), then repelleted in the same rotor assembly for 5 min at 3,000 r.p.m., 0°C . The nuclear pellet was then resuspended at 500 $\mu\text{g ml}^{-1}$ in ice-cold buffer A. To 18- μl aliquots of this was added 2 μl of differing dilutions of DNase I in buffer A; these reactions were incubated for 30 min at 37°C before termination by addition of 1 μl of 0.5 M EDTA pH 8.0. RNase was added to a final concentration of 20 $\mu\text{g ml}^{-1}$ and after a further 30-min incubation at 37°C , proteinase K and SDS were added to 50 $\mu\text{g ml}^{-1}$ and 0.25%, respectively, and the samples left overnight at 37°C . Sample volumes were increased to 100 μl before extraction with phenol/chloroform and chloroform, followed by ethanol precipitation. Resuspended DNAs were restricted overnight with *Bgl*II, electrophoresed on 0.8% agarose gels, transferred to nitrocellulose⁴¹ and hybridized with a ^{32}P -labelled *Bgl*II/*Nco*I fragment (Q in Fig. 1) prepared as described elsewhere⁴².

that these secondary structures observed *in vivo* may be elicited *in vitro* by DNA supercoiling.

We speculate that our observations are best interpreted by a mechanism involving both *cis*- and *trans*-acting components, and envisage a scenario whereby the SV40 early control region binds a *trans*-acting factor(s) which in turn direct(s) the binding of a DNA gyrase-like activity that induces DNA supercoiling. DNA sequences in the proximity of the globin hypersensitive site, with a propensity to form altered secondary structures under superhelical stress, adopt conformations which directly or indirectly discourage the placement of nucleosomes at the hypersensitive site. Supercoiling has already been implicated in generalized DNase I sensitivity²⁵ as well as transcriptional activity²⁶. This, together with the recent observation that the SV40 enhancer region is the major site of action of drug-induced cleavage by

Fig. 4 Analysis of a SV40-*Xenopus* recombinant genome lacking the viral late region. **a**, Map of pJYM $\beta_1\Delta 1p$. This construct is identical to pJYM β_1 except that the *EcoRI*/*PvuII* fragment containing viral late sequences has been removed, and the *Xenopus* globin gene fragment has been inverted. **b**, S_1 nuclease analysis of RNA isolated from HeLa cells transfected with pJYM $\beta_1\Delta 1p$. Probes, markers and methods as for Fig. 2. The *in vivo* RNA lanes contain 1.0, 10, 100 and 1,000 ng of total cytoplasmic RNA isolated from *X. laevis* erythroblasts. **c**, DNase I analysis of nuclei isolated from HeLa cells transfected with pJYM $\beta_1\Delta 1p$. Methods as for Fig. 3. The hypersensitive site of the *Xenopus* β_1 -globin gene is marked C.

mammalian DNA topoisomerase II²⁷, lends credence to this model. Whatever the mechanism of the induction, our data clearly demonstrate that hypersensitive sites can be induced *in vivo*.

We thank J. Allan, M. E. Walmsley and J. G. Williams for critical reading of the manuscript, F. Grosveld for the HeLa cells, and Nicola Podmore and Nick Ansell for helping to prepare the manuscript. This work was supported by a SERC studentship to T.E. and MRC project grant G8400878CB to R.K.P.

Assembly of microtubules from nucleotide-depleted tubulin

P. M. Bayley & E. J. Manser

Division of Physical Biochemistry, National Institute for Medical Research, Mill Hill, London NW7 1AA, UK

In vitro assembly of microtubules from tubulin is considered to have an absolute requirement for added GTP (or a non-hydrolysable GTP-analogue)¹ involving binding at the E(exchangeable)-site located on the β -subunit of the tubulin dimer². By contrast, GDP inhibits assembly. Nucleotide hydrolysis has been implicated in the dynamic properties of microtubules^{3,4}, treadmilling⁵ and mechanical coupling⁶. Here we demonstrate that assembly is not necessarily dependent on the presence of GTP at the E-site; microtubules can be formed efficiently in the absence of GTP in the presence of pyrophosphate. These microtubules, which have normal morphology and lability at cold temperatures, contain N(non-exchangeable)-site GTP and a significant proportion of E-site GDP. This demonstrates the possibility of direct incorporation of GDP-containing tubulin dimer during assembly which probably derives from microtubule-associated protein (MAP)-containing oligomers. This finding has important implications for the mechanism of microtubule elongation. The effects of pyrophosphate suggest that charge neutralization by the bidentate ligand is an essential step in promoting microtubule assembly, and that this interaction involves only a minimal conformational change in the protein.

Studies of nucleotide-depleted tubulin are restricted by high nucleotide affinities⁷ and protein instability⁸⁻¹⁰. We have quantitated the removal of E-site GDP by alkaline phosphatase¹¹, using HPLC to follow nucleotide hydrolysis. The progressive loss of GDP (at 20 °C) is faster and more extensive from tubulin dimer than from microtubule protein (tubulin + MAPs). After treatment for 25 min, the assembly capability of this microtubule

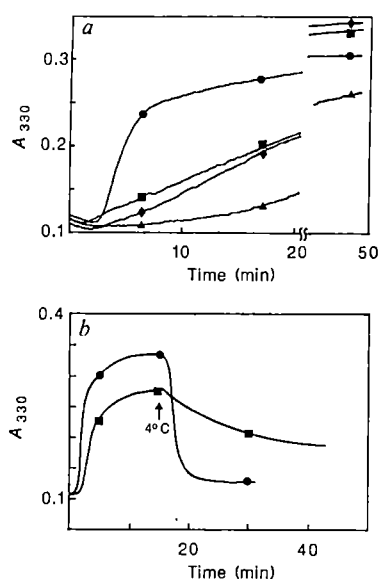

Fig. 1 Pyrophosphate-induced assembly of nucleotide-depleted microtubule protein at 37 °C in the absence of GTP. *a*, Absorbance (330 nm) of microtubule protein (1.2 mg ml⁻¹) treated with alkaline phosphatase for various times at 20 °C, before addition of 3 mM pyrophosphate and incubation at 37 °C in the absence of GTP. The protein was incubated with alkaline phosphatase for 0 (▲), 10 (■) and 25 (●) min. Control (◆), no fast assembly is observed after treatment with alkaline phosphatase for 25 min in the absence of pyrophosphate. *b*, Assembly (37 °C) and disassembly (4 °C) of microtubule protein in 1 mM GTP (●) and of alkaline phosphatase-treated microtubule protein in 3 mM pyrophosphate (■). Protein concentration, 1.2 mg ml⁻¹.

protein (on re-addition of 1 mM GTP, plus 3 mM pyrophosphate to inhibit further alkaline phosphatase action) is >90%, showing that nucleotide removal is reversible.

If pyrophosphate is added after alkaline phosphatase treatment (but without subsequent addition of GTP) a specific pyrophosphate-induced microtubule assembly is observed (Fig. 1). Pyrophosphate added to the nucleotide-depleted microtubule protein (containing 40% E-site GDP) causes a rapid increase in turbidity at 37 °C (Fig. 1*a*, circles), superimposed on the more gradual background increase. The rapid process is caused by microtubule formation (see below); it does not occur if the pyrophosphate is either omitted or added for shorter periods (Fig. 1*a*). Neither phosphate, sulphate nor triphosphate can substitute for pyrophosphate. There is maximal effect at 3–5 mM pyrophosphate, whereas higher concentrations of pyrophosphate are inhibitory. Although prior addition of 1 mM GDP inhibits the rapid effect, there is little effect with addition at plateau: the pyrophosphate-induced assembly does show partial cold lability (Fig. 1*b*).

To eliminate potential effects of dephosphorylation of MAPs by alkaline phosphatase, nucleotide-depleted tubulin dimer was prepared from phosphocellulose-purified tubulin by treatment with alkaline phosphatase for 15 min; the resultant tubulin contained ~20% E-site GDP. Following addition of heat-treated intact MAPs¹² (not exposed to alkaline phosphatase), the nucleotide-depleted tubulin dimer assembled at 37 °C with 3 mM pyrophosphate.

Electron microscopy shows microtubules of normal morphology in the pyrophosphate-induced assembly. The microtubules show well-defined protofilament structure and the rough-walled appearance characteristic of the presence of MAPs (Fig. 2*a*). These microtubules are distributed uniformly throughout the samples (Fig. 2*b*). After disassembly at cold temperatures only amorphous material is seen. When alkaline phosphatase-treated microtubule protein is incubated at 37 °C without pyrophosphate, similar amorphous material is produced (Fig. 2*c*). The microtubules are relatively short compared with those assembled with microtubule protein plus GTP. Micro-

tubules of normal morphology are also formed from nucleotide-depleted tubulin dimer with MAPs as described above (Fig. 2*d*).

The nucleotide content of the pyrophosphate-induced microtubules was analysed by HPLC (Table 1). The initial Sephadex G-25 treated protein contains 1/1 molar ratio GTP/GDP; the E-site nucleotide is >97% GDP. The GTP content indicates tightly bound nucleotide at the N-site, which serves as a marker of the proportion of tubulin retaining structural integrity. Alkaline phosphatase removes GDP from the E-site. On resuspension of the 37 °C microtubule pellet at 0 °C, 86% of the nucleotide-containing tubulin appears in solution, and thus derives from cold-disassembled nucleotide-depleted microtubules. From the GDP/GTP ratio, these microtubules contain nucleotide in the proportion 0.5 mol E-site GDP per mol N-site GTP. Using ³H-GDP, this GDP is shown to derive entirely from E-site GDP bound to tubulin before assembly.

Our results show that nucleotide-depleted microtubule protein can be assembled in the absence of GTP into morphologically

Table 1 Nucleotide content of pyrophosphate-induced microtubules assembled at 37 °C from nucleotide-depleted microtubule protein in the absence of added GTP

	GTP	GDP	GMP/Guo	Total
Microtubule protein (Sephadex G-25 eluate):	100	94	4	(198)
After alkaline phosphatase treatment and assembly at 37 °C:				
S1	86	38	75	(199)
P1	52	20	78	
P1	29	14	3	(196)
0 °C resuspension of P1:

P2	0	0	0	
Ratio S2/P1 (%)	86	86		

Alkaline phosphatase (40 U ml⁻¹) was added to 2.0 mg ml⁻¹ Sephadex G-25-treated bovine microtubule protein¹⁵ (25 min at 20 °C), followed by addition of 3 mM pyrophosphate. After incubation at 37 °C for 15 min, centrifugation (for 5 min at 140,000g in the Airfuge; A100 rotor) of the sample gave a supernatant (S1) and pellet (P1). After resuspension of P1 at 0 °C for 30 min in MEM100 buffer¹⁵, centrifugation gave supernatant S2 and pellet P2. The nucleotide content (mean data of seven experiments), was assessed by HPLC and is expressed relative to initial N-site GTP as 100%; bracketed figures indicate total nucleotide recovery at different stages. Electrophoresis and densitometry of Coomassie blue-stained SDS-polyacrylamide 7.5% gels shows that 47% total protein is pelleted in P1; this material shows a normal ratio of MAPs to tubulin (16% HMW1 and 2). Guo = guanosine.

normal, cold-labile microtubules. There is no evidence that contaminating GTP is responsible for the assembly. We observe short microtubules, indicating efficient nucleation; pyrophosphate is implicated in both the nucleation and elongation processes.

It is striking that the pyrophosphate-induced assembly of nucleotide-depleted microtubule protein gives microtubules which contain substantial proportions of tubulin-GDP. The mechanism of tubulin-GDP incorporation during elongation of microtubules is controversial^{1,13}. Isotope labelling¹⁴, assembly kinetics¹⁵ and time-resolved X-ray scattering¹⁶ techniques indicate direct incorporation of oligomeric fragments into assembling microtubules. The E-site GTP/GDP content of assembling oligomeric fragments is not well-defined. We have shown, however, that in nucleotide-depleted microtubule protein the GDP-tubulin is entirely associated with MAP-containing oligomers. Our present work therefore raises the possibility that fragments containing substantial proportions of tubulin-GDP could be incorporated as such, that is, without prior conversion to tubulin-GTP. We have recently demonstrated¹⁷ that this occurs for the assembly of microtubule protein induced by the GTP analogue GMPPCP. This indicates a minimum requirement for GTP (or an analogue such as GMPPCP or pyrophosphate), possibly at the elongation site, but not necessarily within the

Fig. 2 Electron micrographs of products of assembly with nucleotide-depleted microtubule protein or tubulin plus MAPs at 37 °C with pyrophosphate. Nucleotide-depleted protein was prepared by treatment with alkaline phosphatase at 20 °C as described in Fig. 1 legend; microtubule protein (*a-c*) was incubated for 25 min, tubulin dimer (*d*) for 15 min. *a*, Addition of 3 mM pyrophosphate before 37 °C incubation; *b*, low-magnification view of *a*; *c*, control 37 °C, no pyrophosphate; *d*, nucleotide-depleted tubulin dimer plus normal MAPs (see text) incubated at 37 °C with 3 mM pyrophosphate. (Samples *a* to *d* were prepared for electron microscopy by negative staining as described in ref. 15.)

oligomeric fragment itself. Thus, the nucleotide requirements for assembly of microtubule protein appear to be less stringent than those for pure tubulin dimer.

Direct interaction of pyrophosphate with tubulin has been shown by competition experiments with ^3H -GDP (unpublished data). As a mechanism for pyrophosphate-induced assembly, we propose that this ion binds to tubulin at the E-site in locations corresponding to the high-affinity sites for β - γ positions of GTP. The pyrophosphate ion promotes assembly of nucleotide-depleted tubulin without inducing major secondary or tertiary structural changes^{18,19}. The adoption of an assembly-competent state of tubulin could therefore require no more than the simultaneous occupancy of two potentially adjacent positively charged sites by an appropriate bidentate negatively charged ligand, of which pyrophosphate is a simple example. We suggest that by such an alignment of two protein domains, a minimal protein conformational change facilitates the required interactions for polymerization.

We thank Dr Milan Nermut and Felicity Butler for ultrastructural procedures and Dr Stephen Martin for kinetic analyses. E.J.M. is supported by an MRC postgraduate studentship.

Our knowledge of the structure of condensed matter has been based primarily on spectroscopic methods that measure first-order pair correlations of atomic arrangements and thus provide interatomic distances (for example neutron and X-ray scattering). Bond angles are given by higher-order correlation functions, and such information can be provided by X-ray absorption near-edge structure (XANES) spectroscopy^{1,2}, the features of which are determined by multiple scattering of photoelectrons whose paths

Fig. 1 Experimental XANES spectra (a-d) of a single MbCO crystal for different orientations of the crystal with respect to the polarization vector \vec{E} . The crystal was rotated from the $\vec{E} // \hat{a}^*$ (curve a) to the $\vec{E} // \hat{c}$ (curve d) orientation. The calculated angles φ between \vec{E} and the haem normal \hat{n} are: a, 28°; b, 41°; c, 62°; d, 85°. The experimental XANES spectrum of MbCO in solution is shown dotted.

begin and end at the selected absorbing atom. We report here angular-resolved XANES spectroscopy of a single crystal of carboxymyoglobin (MbCO). The large dichroism of the X-ray absorption of the crystal can be fully interpreted by multiple-scattering theory which allows the determination of Fe-ligand bond angles. The analysis of the identified multiple scattering features due to CO in high signal-to-noise-ratio spectra of protein in solution has allowed the determination of the variation of CO bond angles. This opens the way to the determination of subtle structural features due to bond angle variations in proteins in solution which are relevant to an understanding of the characteristics of proteins at the atomic scale.

Knowledge of Fe-C-O and Fe-O₂ bond angles in solution is fundamental to the understanding of reversible molecular binding of diatomic molecules in haem proteins, but current data are limited to results obtained by crystallography. In fact, only infrared CO stretching and ¹³C nuclear magnetic resonance (NMR) spectroscopy are available to probe CO bonding in proteins in solution; moreover, many factors affect the spectroscopic signals and no simple interpretation has been established in terms of protein structure^{3,4}. XANES spectroscopy is useful in that it is a direct structural probe which can be used to study both crystals and solutions.

We first applied XANES spectroscopy to a MbCO single crystal, a system which has been extensively studied by crystallography. The photoelectron multiple scattering resonances in the direction of CO have been identified which probe the three-atom correlation function and therefore give the C-O bond angle. The Fe-C-O configuration has been found to be bent, with a Fe-C-O bond angle of ~150°; this agrees qualitatively with neutron diffraction data⁵, although that technique is subject to large errors.

We then used the XANES method to study the Fe-C-O bond angle in haem proteins in solution. The infrared CO stretching signal in MbCO changes on going from crystal to solution⁶, and this has led to the suggestion that the FeCO configuration is different in solution. On the other hand, La Mar *et al.*⁷ found no difference between the ¹³C-NMR signal of MbCO and the

Fig. 2 Theoretical angular resolved XANES. a, The experimental features A, B, D, E and F due to the scattering in the haem plane, $\vec{E} \perp \hat{n}$, are predicted by the theory. b-d, The $\vec{E} // \hat{n}$ XANES curves for various CO bond angles. The best agreement between the theoretical and experimental spectra was found for the Fe-C-O configuration at $\theta = 150^\circ$.

unhindered synthetic haem model, and suggested that there was no distortion of the FeCO configuration in MbCO in solution. This is in contrast to the bent configuration observed in crystals. We have found that MbCO in solution shows a Fe-C-O configuration that is bent at $\theta \approx 150^\circ$, as occurs in the crystal. However, for carboxyhaemoglobin (HbCO) in solution we found $\theta = 165^\circ$ whereas crystallographic studies of HbCO crystals found a smaller value of $\theta = 136^\circ$ (ref. 8).

A large ($5 \times 3 \times 0.8$ mm) MbCO single crystal (space group P2₁) was oriented in a collimated X-ray synchrotron radiation beam completely intercepted by the crystal. The XANES spectra were measured by recording the intensity of the FeK α fluorescence as a function of the X-ray photon energy, and the crystal was rotated in steps around the *b*-axis from the $\vec{E} // \hat{a}^*$ to the $\vec{E} // \hat{c}$ orientation, where \hat{a} and \hat{c} are the crystallographic axes and \vec{E} is the polarization vector. The data on the crystals were recorded using synchrotron radiation sources at Daresbury Laboratory and those on the 5 mM HbCO, MbCO and MbCN solutions were recorded at Frascati Laboratory.

Figure 1 shows the angular resolved FeK XANES of the MbCO single crystal. The polarized X-ray absorption spectra can be classified according to the angle φ between \vec{E} and the haem normal axis \hat{n} . The MbCO spectrum for $\vec{E} // \hat{a}^*$ ($\varphi = 28^\circ$) is mostly due to multiple scattering along the haem normal and for $\vec{E} // \hat{c}$ ($\varphi \sim 86^\circ$) the spectrum is mostly due to photoelectron multiple scattering in the haem plane. Features C₁ and C₂ clearly arise from photoelectron multiple scattering along the normal direction, while features A, B, D, E and F arise from scattering in the haem plane. All are present in the spectrum of MbCO in solution (Fig. 1).

The theoretical FeK XANES of MbCO was calculated using the full multiple scattering approach (refs 2, 9-11 and S. Hasnain, A.B. and S.P., unpublished), in which the absorption cross-section for one-electron excitations from a core level is determined by the sum of all scattering paths for the photoelectron which begin and end on the same absorbing Fe atom at the origin. Figure 2 shows several theoretical angular-resolved XANES spectra of MbCO. The atomic coordinates of the cluster

Fig. 3 Experimental XANES spectra of MbCO, HbCO and MbCN in solution. The main difference is the variation of the intensity ratio between peak C_1 and peak D which depends on the bonding angle Fe-C-O(N).

of 30 atoms have been deduced from diffraction data⁵ and polarized extended X-ray absorption fine structure (Fe-N_P = 2.0 Å, F-N_e = 2.09 Å, Fe-C = 1.84 Å) (S. Hasnain, A.B. and S.P., unpublished), and an idealized symmetrical and plane porphyrin ring was used. Figure 2a shows that the theory predicts all the experimental features A, B, D, E, F due to the scattering in the haem plane, while Fig. 2b-d shows the large variation of the \tilde{E}/\hbar spectra obtained by changing the CO bonding geometry. The best agreement between the theoretical spectrum and the experimental results was found for the Fe-C-O bent configuration at $\theta = 150^\circ$. Using the crystallographic coordinates, which have large errors⁵, with Fe-C at 1.78 Å and C-O parallel but displaced from the haem normal axis, we obtain a large disagreement with the XANES experiment.

Finally, having demonstrated the XANES method for a single crystal, we next applied it to determine the bonding geometry of ligands in haem proteins in solution, where diffraction methods cannot be applied. Figure 3 shows the Fe XANES spectra of MbCO, HbCO and MbCN in solution with good signal-to-noise ratio. The main difference between these spectra is the variation of the intensity ratio between peaks C and D , which depends strongly on the Fe-C-O(N) bonding angle. Both by calculation and by comparison with crystal XANES spectra, we find the Fe-C-O angle in solution to be $\sim 150^\circ$, as it is in MbCO crystals.

Theoretical XANES analyses indicate that the Fe-C-O(N) angle is 150° in MbCO, 165° in HbCO and 180° in MbCN in solution. Our results strongly support the Moffat hypothesis¹² that the CN configuration in HbCN is linear and tilted rather than bent. We find, within the sensitivity of the XANES method, that the Fe-C-O configuration is bent in both crystals and solutions, and we estimate that we can easily detect variations of $\Delta\theta = 10^\circ$. We have obtained experimental evidence that the (Fe-C=O) configuration is different in HbCO and MbCO in solution ($\Delta\theta = +15^\circ$ going from MbCO to HbCO) and therefore that the CO bonding is modified by the protein. Crystal diffraction studies have shown a different bent configuration, with $\theta = 136^\circ$ in HbCO (ref. 8). Our data therefore indicate that there is a difference in CO bonding in HbCO in the crystalline and solution phases.

In conclusion, our results show that there is a large dichroism in the X-ray range of the haem protein crystal which can be fully analysed and its bond angles determined quantitatively by XANES. This method can be used to improve our knowledge of the subtle variations that occur in the local structure of proteins and can thus help us to establish the relationship between localized structural changes and the mechanism of protein control of ligand binding in solution close to the protein native state.

We thank M. Perutz for discussions and hospitality at the MRC Laboratory in Cambridge where the MbCO crystal was prepared, and the synchrotron radiation facilities of the SERC Daresbury Laboratory and of the INFN-CNR Frascati Laboratory. This project has been partially supported by the office for international collaboration and GNCB of the Consiglio Nazionale delle Ricerche.

GRANTS & SCHOLARSHIPS

THE UNIVERSITY OF NEW ENGLAND
Equal Opportunity is University Policy
DEPARTMENT OF ANIMAL SCIENCE
POST-GRADUATE SCHOLARSHIP
 (Genetics of Host-Parasite Relationships)

Applications are invited for a postgraduate scholarship funded by the Australian Meat Research Committee. The successful applicant will be expected to enrol for a higher-degree under the supervision of Professor J.S.F. Barker. The research program is co-operative with the C.S.I.R.O. Divisions of Animal Production and Animal Health and has particular relevance to the sheep — haemonchus contortus interaction which includes research into mechanisms of genetic resistance in sheep and in a mouse-nematode model, field evaluation of resistant sheep flocks, computer simulation of the host-parasite interaction and cost/benefit analysis of selection for resistance in sheep populations.

Applicants should have at least an Honours Degree at the level of Second Class Division I in rural or agricultural science, veterinary science or science.

Stipend will be @A\$8,126 per annum. Position No: 583

Further information is available from: Professor J.S.F. Barker, Department of Animal Science, University of New England, Armidale N.S.W. 2351, Australia — Phone 067 73-2223, with whom applications, including the names and addresses of two referees and stating the position no. should be lodged by February 1, 1986.

ARMIDALE N.S.W. 2351, AUSTRALIA.

**INTERNATIONAL BOARD FOR PLANT
 GENETIC RESOURCE (IBPGR).**

The IBPGR invites tenders of a research project to examine the stability of IN VITRO cultures in storage under both slow growth and cryopreservation. Whereas IBPGR is concerned with crop plant genetic conservation proposals may consider the use of explants of species with short generation time and known genetic markers. Proposals should relate to funds for consumables and temporary staff in well equipped laboratories.

Interested laboratories should write for further details to Professor J.T. Williams, IBPGR at either AGPG, Food and Agriculture Organization of the UN, Via delle Terme di Caracalla, 00100 Rome, Italy, Telex 610181 FAO/I or at IBPGR, LNOR, FAO 1001 22nd Street NW Suite 300, Washington DC 20437 Telex 64255.

Preliminary applications should be made before 28th February 1986. Williams Executive secretary IBPGR.

WORKSHOPS

**An EMBO International Workshop on the
 MOLECULAR AND
 DEVELOPMENTAL BIOLOGY OF
 DROSOPHILA**

**will be held at Kolymbari, Crete (Greece)
 June 22-29, 1986**

**The workshop will be cosponsored by the University of Crete
 and the Molecular Biology and Biotechnology
 Institute of the Research Center of Crete**

The objective of the workshop is to discuss selected topics in gene organisation and expression, early development, pattern formation developmental neurobiology and evolution. Approximately 60 participants will be selected by the organizing committee from applicants. The participants are expected to contribute to the subject coverage. Applications should include a short summary of research interests and a brief c.v. if such information is thought to be important in facilitating the selection process. The application deadline is January 20, 1986. Applications should be sent to:

Dr S. Artavanis-Tsakonas, Crete Workshop, Yale University, Department of Biology, P.O. Box 6666, New Haven, CT 06511-8112, USA.

It is expected that a registration fee of \$200 will be remitted upon acceptance. Local expenses in Crete will be covered. Participants are expected to finance their travel to Crete, however, a small number of grants in aid for partial travel support may become available.

The Organizing Committee: M. Akam (University of Cambridge), S. Artavanis-Tsakonas (Yale University), M. Ashburner (University of Cambridge), A. Carpenter (University of California), A. Garcia-Bellido (University of Autonomia, Madrid), W. Gehring (University of Basel), W. Gelbart (Harvard University), D. Hogness (Stanford University), H. Jackle (Friedrich Miescher Institut, Tübingen), F. Kafatos (Harvard University), D. Kankel (Yale University), K. Louis (Crete University), E. Meyerowitz (California Institute of Technology), G. Morata (University of Autonomia, Madrid), J. Nusslein-Volhard (Friedrich Miescher Institut, Tübingen), G. Rubin (University of California, Berkeley), M. Scott (University of Colorado). (NW752)V

SEMINARS & SYMPOSIA

**CALL FOR PAPERS
 SIXTH INTERNATIONAL OCEAN DISPOSAL SYMPOSIUM**

21-25 April 1986

Asilomar Conference Center
 Pacific Grove, California

The symposium will focus on:

- * Persistent plastics, fish nets, and their effects
- * Effects of contaminants on fisheries
- * Marine pollution in island countries
- * Developments in international conventions

Send a 200-300 word abstract by 10 February 1986 to:

Dr. Iver W. Duedall
 Organizing Committee Chairman
 Department of Oceanography and Ocean Engineering
 Florida Institute of Technology
 150 W. University Boulevard
 Melbourne, Fla. 32901 U.S.A.

(NW749)M

CONFERENCES & COURSES

**UNIVERSITY OF BRISTOL
 12 MONTHS MSc COURSES
 BY ADVANCED STUDY
 AND RESEARCH**

are offered in the
 following subjects

Advanced Analytical Chemistry (Inorganic Chemistry)
 Surface Chemistry and Colloids (Physical Chemistry)
 Foundations of Mathematics and Theory of Computation (Mathematics)

Fluid Mechanics (Mathematics)
 Meat Science (School of Veterinary Science, Langford)

The courses in Chemistry and Mathematics normally qualify for SERC studentships; the course in Meat Science normally qualifies for AFRC studentships. Early application is desirable. Further details of the individual courses may be obtained from the Head of Department concerned, University of Bristol, BS8 1TH. Enquiries are also invited for details of opportunities for research leading to the degree of PhD.
